The concept of PPP covers a wide range of situations and is subject to various interpretations. Many definitions exist in the literature. According to the PPP Reference Guide ([Partnership, 2017](#)), edited by a consortium of major international organizations lead by the World Bank, PPP is “a long-term contract between a private party and a government entity, for providing a public asset or service, in which the private party bears significant risk and management responsibility and remuneration is linked to performance.” In this definition, “asset or service” means that both new and existing assets are concerned; it also includes the cases in which the private party is paid entirely by service users, and those in which a government agency makes some or all payments. It encompasses contracts in many sectors and for many services, provided there is a public interest in the provision of these services and the project involves long-life assets linked to the long-term nature of the PPP contract.

An alternative definition ([Sabot and Puentes, 2014](#)) is “a legally binding contract between a public sector entity and a private company where the partners agree to share some portion of the risks and rewards inherent in an infrastructure project.” Anyhow, the choice of the structure is embedded in the legal traditions of the countries, as it appears from the comparison of the guidelines of various countries (see, for instance, [HM Treasury, 2003](#)) and also in the current practices ([Medda et al., 2013](#)).

From this quick review it is clear that in fact PPP does not imply just funding but also other aspects such as risk management, legal responsibility, in fact, the whole management of the project, which can then cover the range between “pure public” management and “pure private” management.

Why use a PPP?

As far as public infrastructure such as essential facilities are concerned, the reasons for public intervention and motivations are numerous. Some are general and linked to the need for developing policies where private initiative is insufficient, such as the emergence of new activities, network effects and needs of coordination. Other ones are related to strategic issues, for instance military purposes. Others are more common and well known by economists; they are linked to market failures. Among them are general market power and customers’ information, which justify the role of Competition Authorities. Other market failures, frequent in transport, are externalities and market power resulting from increasing returns to scale. Increasing return to scale is a common feature of infrastructures. Externalities are most commonly negative, such as environmental externalities, congestion and safety externalities, but some can be positive like the agglomeration externalities. Other reasons of public intervention lie in distributive concerns, or local development issues, for instance in the cases of seaports and airports.

But public intervention has limits from several points of view. The first one is the commonly recognized poor public management vis-à-vis private management. Economic literature has developed this point in two different directions. The first one is the bureaucracy theory (Niskanen, 1971), which stresses the fact that public management is based on the respect of standards and budget constraints, contrary to the private management, which is based on efficiency and search for profit. The second one is the theory of organization (Williamson, 2002), which compares the forms of control in both types of management (Vickers and Yarrow, 1988). It shows that public control is looser than private control. Private firms are acknowledged to have a technological comparative advantage: they are more able to market their products and to fit better the needs—at least the bankable needs. Public authorities may want also to introduce some flexibility so as to circumvent administrative or legal constraints and this goal can be achieved through private management. Private funding is more able to use innovative financial tools. Private access to international and more competitive financing is often sought out, though states may get equal or, quite often, better financing conditions. In some countries, PPP may be a device to alleviate the public budget constraint. It is for instance the case when public authorities are not allowed to levy infrastructure charges, contrary to a private firm. It may be also the case when no infrastructure charge can be levied, but when the concessionaire receives a yearly subsidy from the public authority, as it is the case for the private finance initiative (PFI) in the United Kingdom: this process allows to shorten the implementation of a program for a given amount of money. Another often advocated motivation for PPPs is a great reduction in delays for delivering the infrastructure and related services. But ex-post analyses do not always confirm this belief (see for instance the case of Irish motorway PPPs in Ireland (Reeves, 2005)).

For some items, private and public management are complementary. For example, in the case of risk, some risks such as financial risks, are usually considered as better managed by private firms, and some other risks, such as macro-economic risks, as better managed by the public authority. These considerations draw the pertinence scope of PPP: when private motivations are large, the private firm does better; when public motivations are large, public management is better. In the middle and in the case where motivations are shared lies the PPP pertinence. Also, risk transfer to the private partner entails an inefficient risk-pricing premium that should be compensated by an additional efficiency gain (Makovsek and Moszoro, 2017). This is also true for the frequent case where the PPP generates higher financing costs and high transaction costs—public as private—due to PPP complexity.

But cooperation between these two agents is difficult as their goals are different: the private partner seeks to maximize profit; the public partner seeks to maximize welfare.^a The public authority must induce its private partner to achieve welfare goals without losing the efficiency of private management. How to choose the better PPP arrangement, giving the best public value for money, and should this arrangement be preferred to full privatization or to public management?

How to Manage a PPP?

Let us proceed through the history of a PPP, beginning by the procurement, then the contract and its life.

Procurement Organization

The first decision is whether and how to fragment the missions. From the geographical point of view, the range of possibilities goes from an isolated link or node to the entire network of the country. From the technical point of view, it is possible to put the private partner in charge of either the whole activity, from the initial design to the maintenance and operation of the infrastructure, or in charge of just a part of the process, for instance construction, or operations, or maintenance. Many possibilities exist, such as the well-known BOT (build/ operate / transfer back). A well-designed fragmentation in the technical and geographical dimensions can reduce the market imperfections and/or increase the efficiency of the management. The fragmentation has consequences on efficiency. Many reforms have led to fragmentation of the incumbent firms in order to have smoother and easier to manage organizations. It is for instance the case of the railways reforms in Japan and in South America (Thompson, 2001) where the big incumbents have been geographically split up into several smaller firms.

Fragmentation has also been used for introducing competition. For instance, the European Railways Reform (Commission of the European Community, 1991) was based on the separation between infrastructures and operations; the aim was to isolate operations, which had almost constant returns to scale and could be run in the framework of competition, and to leave apart infrastructures, which clearly have increasing returns to scale and would therefore better be run as a regulated monopoly.

Geographical fragmentation is limited by economies of scale. Building a motorway exhibits large economies of scale up to a length of about 200 km and, above this length, returns to scale are roughly constant (Fayard et al., 2005). The same happens for maintenance: a maintenance center is best fit for a length of a few hundred kilometers (Link, 2006). The geographical fragmentation is also influenced by the size and nature of externalities (Meunier and Quinet, 2007): fragmentation of two adjacent links can induce double monopolization.

Fragmentation is also a means to set up yardstick competition^b when it is possible to create several operators; and the larger the number of operators is, the more efficient the competition may be (Bouf and Lévêque, 2004). Vertical fragmentation is limited by

^a Though the public objectives may also be multiple and possibly contradictory (e.g., public debt reduction, development of transport network, environmental goals, etc.), which may make more complex the decision to choose a PPP, but also its management and regulation.

^b Yardstick competition is a regulatory means, either formal or informal, of putting pressure on a firm through comparison of its results (in terms of costs, quality, or demand) with the results of similar firms.

potential economies of scope. For instance, in the case of railways, several authors consider that economies of scope between infrastructures and operations are too large to make fragmentation interesting (Basso and Jara-Diaz, 2005). But this argument has never been presented in the case of air transport, which economies of scope are quite doubtful (Oum and Fu, 2008). The recommendations of the bodies in charge of PPP design insist on these complementarities. An important issue is to see whether there are or not complementarities between building and maintenance, since they command the issue of separating or not these activities (Iossa and Martimort, 2008).

Contract Regulation

If regulation were perfect, i.e., if the regulator or the public authority knew perfectly well the ability of the private partner and were able to perfectly observe its effort (no information asymmetries), and if there were no uncertainty, then in this first best situation, the regulation could reach the first best optimum. The real world is different. None of these conditions is fulfilled, and the contract has to minimize the gap with the first best situation, dealing with risk, information issues (adverse selection and moral hazard) and transaction costs.

Risk

The agents take a risk premium depending on the risk level of the project. We have a poor knowledge of risk premiums. Risk premiums depend also on the agent's risk aversion; from that point of view, public operators are in general less risk averse than private ones. Risks are usually classified as political risk (changes in taxes, in standards, and public decisions that may modify the profitability of PPP), technical risk (mainly during the building phase) and commercial risk (demand risk).

The general principle of risk sharing is that each risk should be shared between the agents according to two factors: the agents' respective ability to get information on and to deal with this risk, and their risk aversion. From this point of view, the demand risk of a motorway could be mainly borne by the franchiser since he can influence it by his actions (for instance through deciding to improve or not a parallel road) and the concessionaire has no large possibility to act on it and furthermore has a larger risk aversion. The situation would be different if the concessionaire had the possibility to influence the traffic level—more generally the demand—by means of some marketing action (as it may be the case for airports). Nevertheless, in case the PPP directly gets revenues from the users, the private partner may, through adjusting the price level or differentiating the prices, try to increase its profit at the expense of the users: the public authority has then to set in the contract the degree of freedom left to the private partner. Besides direct revenues stemming from the infrastructure by itself, the private partner may also have opportunities to take advantage of other assets or markets linked to the PPP (duty-free sales in airports, shops in stations, land development, etc.). The recommendations for PPP management insist on the risk sharing issues along the above lines and their consequences for productivity and costs.

Some studies have enlightened the effects of a more or less tight regulation on productivity (Cantos et al., 1999; Gagnepain and Ivaldi, 2002). A tight regulation is measured by the “distance” between the private firm and the public authority as well as the risk sharing agreement (price-cap or cost plus regulation). It appears that the tighter the regulation and the farther the agent from the public authority, the lower the production cost is; here again, the focus of these studies was on operations more than on infrastructures. These studies show that it is possible to increase the effort of the private partner through an increase of its risk exposure. But its information rent^c is then increased, as shown by theory. There is then a trade-off, widely studied by theory (Laffont and Tirole, 1993), between the effort and the rent.

Reducing this asymmetry is a major objective of the public authority, as shown for instance in the PFI recommendations (Estache and Serebrisky, 2004). Asymmetric information is one of the major causes of the regulatory inefficiency (indirect capture); this gives the operator a lever to influence the public authority, induce it to make wrong judgments and estimates and lead it to decisions that are bad for welfare but good for the operator.

The contract life is concerned with the contract duration and possible renegotiations. The contract duration must, first, be long enough to cover a sufficient proportion of the total cost through tolls or charges. Given that the cost of infrastructure is very high in general, this point advocates for long durations. Another argument advocates in the same direction: the operator must bear the fruits of its decisions, especially in case of long-term investments. This leads to proportionate the length of the contract to the lifetime of the work. Conversely, the length of the contract should not be too long in order to avoid a too large information or risk rent. Theoretically, demand risk can be coped with using endogenous duration contracts (Nombela and de Rus, 2004): in broad outline, when demand is lower than forecasted, the duration of the contract is postponed, and reversely when the demand is larger. In the case of long duration, it often happens that the risky alternatives are numerous and even difficult to enumerate, even more hard to assess; also, it is difficult for both parts to credibly commit that they will never renegotiate, even in case of the bad outcomes of the risks. In such situations, it is simpler to sign an incomplete contract with a pre-defined renegotiation process. Such is the case too when the costs of possible errors in a rigid contract are large, or when there is a large degree of trust between the partners (Athias and Saussier, 2018). The exemplary nature or the repeatability of the contract may give reasons for confidence. Furthermore, renegotiations often reveal that the initial PPP design is not always optimal; for instance, the renegotiation of some motorway PPPs in Portugal lead to transferring operational service to the public sector, at a lower marginal cost.

^c Information rent is the additional earning an agent derives from having a private information not available to the other agents with whom he is engaged in a bargain.

Figure 1 PPP in the transport sector.

PPP in the Transport Sector

Perhaps the most important use of PPP is in the transport sector; though there is no exhaustive statistics on the number of PPP by sector, this affirmation is supported by the records of EIB funded projects. Similarly, the World Bank records 4 G\$ in water and sanitation, 70 G\$ in transport and 37 G\$ in energy for year 2015. There are obvious reasons why transport has such a leading place in PPP (Fig. 1).

On the one hand, most transport infrastructure appear beyond the short-term fiscal capacity of public funding sources, while in many situations it is technically possible to levy charges on most of these infrastructures, though those charges are not sufficient to cover all expenses. On the other hand, such infrastructure entail externalities implying public interventions. These reasons have different weights according to the type of transport infrastructure. These points are exemplified for road, which presents simpler characteristics and more examples; some general observations are given for port infrastructure.

PPP in Road Transport

Motivations of private involvement in road mainly stem from funding, as the issues of costs, productivity, technique, innovation and financing should have decreased in developed countries. Road products and services have become standardized and know-how is widely spread and internationally available. Nevertheless, the innovations that may stem from new information and communication technologies (NICT) offer an important potential: motivations related to innovation and reactivity have thus grown in the last 10 years or so. For countries that do not have much-developed road or motorway network and lack strong competencies inside the public sector, the motivation may be high to have private firms bring their ability to optimize costs in relation to local conditions and to optimize the financing mechanisms of infrastructure projects.

Risk and uncertainty in the road sector are rather low. Construction risk is essentially the concern of private, and remains in general low, thanks to the high level of competency available internationally. Demand risk is not much in the hands of the private partner as it cannot take much action on it. The risk to demand is perceived by the infrastructure manager (IM) essentially through the risk to its revenues, and most of this uncertainty disappears once the motorway has come into operation and becomes a brownfield operation. Exogenous uncertainties tend to grow as concerns the macroeconomic trends and petrol prices. The present global economic crisis has put this to light, and this increases demand uncertainty. Social acceptability of infrastructure represents a type of risk that emerged and has been developing more specifically in the last 10–30 years, depending on the countries. It may be better treated by the public partner when, for example, social acceptability is linked to the confidence level in the collective interest of the project.

The competition framework may theoretically be organized by proper allocation of projects inside consistent programming of a meshed network to check any IM from exerting a strong market power while exploiting economies of scale. The latest are mild, since returns to scale are roughly constant above motorway lengths of about 200 km.

As regards market power, the basic idea would thus be to give to the same IM complementary links and to different IMs the links that may be in competition with each other. Though these principles are clear and simple, it is questionable how far they may be put into practice as competition between two parallel motorways is often limited when these motorways are not very close to each other; and in the rare cases where they are close, the equilibrium may be unstable (case of Mexican motorways experience). In practice though, each road link has very diverse users that come from numerous origins and want to go to numerous destinations. Relations of complementarities and competitions between road links are therefore complex, and they change with the meshing of the network.

Another question is: are there strong positive externalities of infrastructure building, operations and maintenance? For motorways these externalities do not seem to be very strong and manageable. When standard techniques are used for road works, it is

possible for the public authority to estimate average maintenance costs and then global costs, and to impose technical choices, whatever the fragmentation of PPP's missions. Bundling the two missions may present another externality for risk management. For example, the concessionaire of the Millau viaduct in France decided to finance the building phase entirely by equity and, after the viaduct was put in operation, to negotiate far better financing conditions than if he had asked outside financing from the beginning. Doing thus, the concessionaire bore the building risk and the risk on initial traffic level, and reduced the total financing costs since at this stage the risk premium asked by the markets was much lower. This decision was made possible because the concessionaire felt it could correctly manage the construction risks, had enough financial capacity for this, and had enough confidence in the robustness of traffic forecasts.

Theoretically, construction and demand risks can be alleviated through more innovative but rarely used devices, such as endogenous duration contracts (Engel et al., 2001). Quite often, demand risk is found to be more directly taken in charge by the private partner when it finds the market is mature enough (other toll motorways exist in the country and have proved to be profitable, confidence in the traffic forecasts). In such scenario, guarantees and subventions may become lower or even disappear.

Demand risk is often subject to risk sharing between public and private partners of the PPP, whether through guarantees given or by setting in the contract an incentive to voluntarily introduce optimal prices based on information which is not too costly to get: for instance, by automatic traffic counters, or by complaints of the users in case of congestion. And, rather than fixing congestion prices, it may be better to fix the required quality level (e.g., a minimal driving speed) and to let the private partner adjust prices accordingly. This is used for instance on SR91 in California and on A86 motorway near Paris, in a more limited form.

The duration of road contracts generally should come, rather naturally, from calculation of the rate of return of initial investment or the technical lifetime of infrastructure; both entail very long durations. A motorway contract's duration is generally in the range of 20–40 years (except cases of endogenous duration mentioned above). Such long durations imply that numerous unforeseen events may occur, and therefore such contracts are, by nature, incomplete contracts.

This situation entails big consequences for the design and regulation of the contracts: it becomes very difficult to include powerful incentives due to the high risk that the contract, due to its long duration, will anyway be renegotiated. Thus, contractual rules for price regulation apply during successive periods of about 5 years, introducing some flexibility in contracts with a rigid rule that would otherwise be valid for the whole duration of the contract. This depends also on demand uncertainty: empirical studies show that concession contracts with high traffic uncertainty are more likely to be flexible (Athias and Saussier, 2006).

But if revenues are linked to the investment level, for instance on the basis of guaranteed rate of return, private partner may tend to over-invest (Averch-Johnson effect). Such could be the case with endogenous duration contracts: when signing the contract, nobody knows when it will end, and lawyers, accountants, and politicians usually dislike this kind of uncertainty.

To our knowledge there is no example wherein a motorway is stopped to be used or destroyed after the end of the contract. The conditions under which the contract reaches its end will therefore focus on the final requirements for infrastructure and equipment quality, with contractual financial penalties to make these requirements credible. Generally, a new contract will be signed to ensure the continuity of motorway operation, with the same private partner or with another.

PPP in Ports

Public motivations in the port sector have varied historically. Once a major economic potential for countries and cities that were built around port activities, economic role of ports has decreased in relative terms, whereas competition between ports increased as globalization developed, especially during the last decades.

Concerns about market power of ports may depend on the context and on the geographical scale. Indeed, unlike motorways, we deal here with international and, for a good part, inter-continental traffic: a transfer of traffic or activities from one port to another one located in the same range may be seen as positive at the local level (regional) of the second port, but neutral at a higher level (country or EU). There are motivations concerning service continuity (ports are still vital for a big portion of the economy), strategic issues (energy, defence, security), and market power of "captive traffic" (industries located inside the port and very near). And, in the recent period, concerns about sustainable development have grown. Indeed, water and air pollution represent important issues on the seaside; so does biodiversity, especially in estuaries and in the large land reserves that many ports still control.

Some peculiarities of ports must be taken into account here: ports are complex interfaces involving many functions, and are only one link in a whole transport and logistics chain. Therefore, coordination is a key competitive item, and public coordination may be seen as more neutral than coordination driven by one of the actors concerned. Still, very rare have been the ports that did cover all functions by public entities: ports are by nature a place of interface between public and private interests, the question here is rather to analyze the degree of implication of the public authorities in this complex interface.

Motivations for private involvement have grown with the competition toughness, which implied high pressure on costs and productivity, but also with the development of new logistics chains and equipment, implying a need for new technical skills, the ability to innovate or adapt reactively to innovation. In this respect the business plan of a port is, as well as the business plan of an airport, much more sophisticated than the business plan of a motorway, where the single parameter at hand of the manager is the infrastructure charge. It is important also to take into account the long-lasting internationalization trend and the concentration trend in the maritime sector and in stevedoring. The container industry especially was quite a revolution, implying not only a mix of public and private funds, but also strategic views on how to develop the industry: new equipment was required, therefore costly investment; and the exploitation of scale economies driving the container development also meant progressively increased standards of capacity for ports. Indeed, the inter-continental container ships have become quite huge and do not seem to have yet reached their full

potential of scale economies. The increased volatility of traffic implied more weight was put on the commercial concerns of ports and more commercial reactivity, as it is easy to lose a client, but very difficult to get him back or to attract new ones. Private management is usually recommended to front such commercial risks. Furthermore, demand risk has grown with the degree of port competition and the loss of weight of ports in the big players' game; now macro-economic risk has added on top of that. Besides demand risk, which may be considered as the main risk, construction risk is rather low, at least for its technical components.

These considerations about the port sector evolution help to understand why we do observe many forms of public involvement in ports from the "fully integrated public port," that is nowadays kind of a white elephant, to the "landlord port" that lets all physical operations to private actors. A "landlord port" only retains basic functions such as "social regulation" (safety) and most of the time (except in the rare cases of full privatization as in the United Kingdom) control over land affectation/lease and basic infrastructure (navigation channels and berths). This is why we will use the term "port entity" (PE) from now on, rather than the more limited term "infrastructure manager" (Brooks and Cullinane, 2006). The complexity of port issues and the need for rapid reaction to (or anticipation of) market changes may advocate for more autonomy to be left to the PE together with more implication of stakeholders in port governance, which make it difficult to build a complete rigid contract as regards investment. In practice, such contractual coordination structures and organization of dialogue between stakeholders may help to reduce information asymmetry by facilitating learning of chain performance conditions (economies of scale and scope, competitive key factors, limiting factors for the port) and in assessing risks and externalities that are not easily seen unless collectively addressed (the usual problem of multi-principal studied by the literature on industrial organization).

As a conclusion, ports are a natural and complex interface between public and private concerns and actors. Though they are precisely located by nature, they intervene in complex international chains and their time scales are simultaneously very long due to their long-lasting assets and the irreversibility of many decisions, and quite short due to the necessity to react quickly to evolutions in demand or to the competitors' actions. The geographical scale of both public and private entities has major importance. The intervention of the private has been growing in a regulatory framework that tends to be enlarged and renewed: international and national legislation, environmental rules, but also contractual risk-sharing and governance of coordination between the multiple port actors.

Airline Demand

The model of supply and demand explains how prices are determined in a market system. It is important for an airline to understand the market demand and the supply for its own product in order to make informed strategic and operational decisions. The demand for an airline's services is influenced by the price it charges, the prices charged by its competitors, the availability of other transport modes, its service quality such as frequency, and in-flight services, its safety record, passengers' income and preferences, macroeconomic conditions, and demand shocks (Vasign et al., 2018). A change in one or more of these factors (except its own price) will shift the demand curve and lead to a new equilibrium price. In the following, some of the factors will be briefly discussed.

First, the demand for air transport is highly responsive to price. Most passengers, even some of the business travelers, are sensitive to airfares (Zhang, 2012). More and more companies have issued the travel policies to control business travel expenses. Previous demand estimations for the developed economies show that the values of air travel price elasticities range from -0.8 to -2.0 (Oum et al., 1993). A recent study on the China and India aviation markets finds that the demand elasticity is about -2.6 in India while is about -1.2 for China (Wang et al., 2018a). This suggests that the major Indian routes have a very price-elastic demand compared with other aviation markets in the world.

Income is one of the determinants of the demand for air services, which is usually proxied by gross domestic product (GDP) per capita. Air service is a normal good and thus the higher income, the higher air travel demand. Studies have shown that demand elasticity with respect to income is close to 2 (Garín-Muñoz, 2006): for instance, if the economy grows by 5%, then the air travel demand would grow by 10%; likewise, if the economy contracts by 2%, the demand would shrink by 4%. This pro-cyclical behavior has important implications for airlines' decisions on route entry and exit, and on aircraft order, purchase, and lease (Zhang and Zhang, 2018).

In addition to price and income, air travel demand is affected by the availability of other modes of transport. Since the new century, high-speed rail (HSR) has emerged as a significant transport mode in Europe and China after its success in Japan for several decades (Zhu et al., 2019). The HSR service has been shown to be a good substitute for air on short/medium-haul routes, sometimes even on long-haul routes. Here, the modal choice is based on the full opportunity cost, that is, the sum of ticket price and journey time cost. The total journey time consists of access time, travel time, and expected "schedule delay" (Behrens and Pels, 2012). For a given origin-destination (O-D) pair, while air mode has a shorter travel time than HSR, it has longer access time including the time of accessing to (and egressing from) the airport/train station, the time spent at the terminals, and the takeoff/landing time (Zhang and Zhang, 2018). Higher frequency will reduce the cost of schedule delay, a measure depicting the deviations from a passenger's preferred time of travel, and increase the visibility of a flight option (Douglas and Miller, 1974). More frequent services reduce expected schedule delays and hence is a more convenient service, which in turn increases demand.

Demand for air travel is also related to distance. The longer the travel distance involved, the fewer trips will be made. This is sometimes referred to as the gravity of law of travel demand: demand falls with the square of the distance between origin and destination, similar to the gravity law in physics. Much of the airline literature on O-D bilateral air traffic flows employs a gravity model. However, unlike the gravity models in the international-trade literature where the distance variable is consistently statistically significant, distance does not seem to be a good proxy for bilateral cost after airline deregulation (or liberalization) that first started in the United States in 1978 and then spread to other countries, especially in the markets where low-cost carriers (LCCs) are present (Zhang et al., 2018a). The average airfares have been declining in the last 30 years as a result of strong competition in the airline industry. Discounted airfares are prevalent on short-distance and particularly on long-distance routes. Therefore, geographical distance is no longer a good proxy for travel cost. That distance plays a smaller role in air transport may also be due to other reasons. First, on short-distance routes (say, less than 300–400 km) few air trips are made, owing to an increased cost/time ratio relative to alternative modes such as HSR or automobiles. Second, very long distance eliminates alternative transport modes (such as HSR and cars), which may increase the demand for air services (Zhang and Zhang, 2018).

Overall aviation safety across the world has steadily improved over the last three decades. However, in 2018 there were 15 crashes causing 556 fatalities, compared with 44 deaths in 10 accidents in 2017. Safety and security are top priorities in airline management

since both are important determinants for air travel demand. Air travel drops whenever there is a major air disaster, and so there has long been a major emphasis on safety and security regulation in aviation. Safety regulation involves policies and procedures to minimize the risks of failures in the design and operation of airlines and airports. Security concerns deliberate sabotage or other acts to cause harm to air operations and the traveling public. Since September 11, 2001, security has become the highest priority of the global aviation industry and many governments. However, increases in safety and security can only be justified when the benefits are greater than the costs. The full benefits are difficult to quantify in reality and research into the economics of safety and security is still rare in the airline literature (Vasigh, et al., 2018).

Airline Costs and Production

While consumers form one side of the market—the demand side, airlines form the supply side. As with other industries, to provide air transportation services airlines use various inputs, such as labor, capital, fuel, and materials. Therefore, the main determinants of the supply of air services include ticket price, the prices of inputs such as fuel and labor, airport charges, aircraft costs, maintenance costs, government regulations, and technology (Vasigh et al., 2018). Random factors such as weather and strikes also affect the provision of air services.

Fuel cost is the largest cost component for most airlines, which accounts for around 20%–50% of the total costs depending on the type of airlines and time (Koopmans and Lieshout, 2016). A flight sector comprises the ascent and decent phases as well as the cruise phase. During the cruise, the fuel cost is proportional to the route distance. Fuel costs can also differ substantially from one country to another, due mainly to the differences in taxes and transport costs. Airlines pay fuel prices at airports they serve, and thus the average price paid by a carrier is roughly a weighted average of fuel prices of the destinations it serves. Although the fuel price is largely out of an airline's control, some airlines are keen to use more fuel-efficient aircraft to save costs by purchasing (or leasing) new planes. Other airlines choose to replace the seats, television monitors, and even the beverage carts with newer and lighter versions (FAA, 2011). Aviation fuel is a major contributor to emissions. Interestingly, in the EU, aviation fuel has long been tax exempt and aviation fuel tax has been called for to help Europe to meet its climate targets.

As fuel cost has replaced labor cost as the largest cost component for many airlines, fuel hedging has been frequently used to reduce airline exposure to unexpected changes in fuel price. This is because these days it is difficult for airlines to pass the rise in fuel cost on to consumers in a deregulated and competitive operating environment. Interestingly, however, the benefit of fuel hedging appears controversial. Some studies report a positive impact of fuel hedging on the airlines' firm value (Sturm, 2009), while some other studies claim that hedging does not necessarily affect a firm's market value (Jin and Jorion, 2004), and that sometimes it could have a negative but insignificant impact on operating costs (Lim and Hong, 2014). This means that the actual benefit of fuel heading could be negligible. Therefore, it seems that merely engaging in fuel hedging is not sufficient to achieve cost reduction.

In the last two decades, the legacy airlines have managed to reduce their labor costs through various ways. Declaring bankruptcy is one way through which the contract conditions can be changed and the benefits and pensions can be reduced. American Airlines, Delta, Northwest, United, US Airways, and Continental all used this way to reduce the labor costs. Some of them went through bankruptcy twice. Qantas suffered huge financial losses from 2011 to 2014 and it announced to cut 5000 jobs, 15% of its workforce in 2014 as well as other cost control measures. In 2015, Qantas returned to profits. It should be noted that LCCs do not necessarily pay lower wages than full services carriers do, but they may require staff to perform multiple tasks to save costs (Vasigh, et al., 2018).

Airlines operate in a dynamic environment with a great number of uncertainties, and with airline revenues and costs being influenced heavily by overall economic activities. An important financial decision is the decision to buy or lease aircraft. Operating lease and direct purchase with bank finance are two commonly used methods of financing the aircraft acquisition. Should an airline purchase and own the aircraft? If purchased, should the airline pay 100% cash or borrow some funds for the purchase? These decisions depend on the market conditions and the airline's financial conditions (Accession Capital Corp, 2003). There is no one method that is superior to another. Interest rates, discount rates, lease rates, and depreciation are relevant costs and should be taken into account when making these decisions (Zhang and Zhang, 2018). Today, around 40% of the worldwide fleet is owned by leasing companies. The share of leased aircraft was only 20% in 2000 and is expected to reach 50% in 2020.

It is believed that airline cost per seat declines with the size of aircraft (up to some threshold). Furthermore, the cost per passenger falls as the percent of seats sold on a flight (the "load factor") rises, since much of a flight's cost is fixed regardless of the number of passengers flown (Zhang and Zhang, 2018). These relationships do not necessarily imply the existence of economies of scale in airline operations, however. In fact, some researchers claim that economies of scale are negligible or non-existent (White, 1979). This is because adding or dropping cities from an airline's network does not raise or lower unit cost. In contrast, sizeable economies of traffic density seem to exist up to fairly large volumes of traffic (Caves et al., 1984). This means that the airline industry is more likely to exhibit economies of density instead of economies of scale, and that the cost savings can be achieved through the intensive and efficient use of larger aircraft with higher load factors (Brueckner and Spiller, 1994).

Airline Pricing

For most airline markets, there are only a few airlines competing against each other. Therefore, airline markets are typically oligopolistic (Levine, 1987; Borenstein, 1992). Numerous theoretical and empirical studies have attempted to examine the pattern

of airline pricing and price dispersion, many of which have found that price discrimination, new technology and innovation, the presence of LCCs, market structure, deregulation and airline merger and alliance are key determinants of the variations in airline pricing (Borenstein, 1985; Brueckner and Spiller, 1991; Berry, 1992; Brander and Zhang, 1990, 1993; Zhang et al., 2018b).

Price discrimination is traditionally seen as one of the sources of price variation, especially in the airline industry (Cross, 1995; McGill and van Ryzin, 1999). There are three types of price discrimination: first degree, second degree, and third degree. Under first-degree price discrimination, the entire consumer surplus is transferred to the firms, which is unlikely in reality, as airlines do not usually have the ability to determine a consumer's reservation price. Second-degree price discrimination is the practices of charging consumers difference prices for different quantities of the same product consumed. Probably a frequent flyer program may fall within this type of price discrimination as the points awarded to the passengers can be used later, which is a special kind of discount and consumers do not need to pay for the points at the time of purchasing the ticket. Third-degree price discrimination refers to the charge of difference prices to different consumer groups such as male and female, children and adults. Many airlines offer corporate travel programs to companies and give cheaper contract prices, which is a practice of third-degree price discrimination.

The emergence of new technology has enhanced price discrimination. Some researchers argue that airline pricing falls somewhere between first and second-degree price discrimination because of the use of computer reservation system (CRS), later renamed as Global Distribution System (GDS) (Kons, 1999). This is because the creation of a large number of prices possible by the GDS allows the airlines to acquire more consumer surplus than second-degree discrimination offers. The GDS provides virtual real-time connectivity between thousands of suppliers of travel inventory (e.g., airlines, hotels, car rental, and tour operators) and hundreds of thousands of retail sellers of travel products (Sismanidou et al., 2009). The system has significantly improved airlines efficiency in attracting and retaining customers and driving sales through travel agents. American Airlines was a pioneer in using a sophisticated yield management program to attract both the high yield and low yield passengers in the 1980s, which gave it huge competitive advantage in the battle against the newly established carriers such as People Express Airlines following airline deregulation (Smith et al., 1992; Cross, 1995). For example, the carrier used "Ultimate Super Saver" fares to match People Express's lowest prices (Vasigh et al., 2018). This price type required 21-day advance purchase restrictions in order to draw in only the most price-sensitive travelers. The airline also controlled the number of "Ultimate Super Saver" fares available on each flight in order to make seats available to high-yield passengers (Cross, 1995). By this way, the airline was able to generate profit from both low-revenue and high-revenue passengers. In contrast, People Express could only capture low-revenue passengers with its single fare class reservations system.

In the 1990s, airlines began to reduce the commission paid to travel agencies and the distribution system by increasing their direct sales through the Internet. The Internet enables airline products accessible 24/7 and allows the airlines, the distributors, and the customers to communicate and interact with each other globally and efficiently (Timmers, 2000). In particular, LCCs took advantage of the internet to developed simple distribution strategies and bypass travel agents and GDSs, which is a key factor for the success of this business model. For example, JetBlue and Southwest Airlines sell up to 90% of their tickets directly through their websites. China's Spring Airlines has tried many ways to save costs, including the use of its own CRS and encouraging online purchases. The Internet is now its main channel of distribution and passengers who purchase tickets through a ticketing office have to pay an extra purchase fee. Its average ticket price was about 30% lower than the industry average price. With the advantage of low price ticket, Spring Airlines maintained a high load factor of about 95% through offering low airfares, well above the industry average of 70% (Zhang and Lu, 2013).

The recent advance in new technologies of the artificial intelligence, big data, and virtual reality can lead to a revolution in airline pricing and personalization concepts (Krämer et al., 2018). Dynamic pricing as a result of the capability of analyzing big data allows airlines to predict with a high degree of certainty customer demand and preferences, which makes it possible for the airlines to offer a fare that is closer to the customers' demand (Hammou et al., 2018). Based on the customers' browsing pattern, the artificial intelligence system tracks the changing volume of search requests from the airline website or other search engines. The airlines can make prompt changes to the airfare, if needed.

Airline pricing is also associated with market concentration. An increase in concentration (e.g., as a result of airline mergers and alliances) may confer the airlines with market power (Zhang and Round, 2009). Following airline deregulation there was a wave of airline mergers in the 1980s that were supported by the Reagan administration. In the 1990s, there was a proliferation of airline alliances, both international and domestic. Today there are three major global alliance groups—namely, Star Alliance, One World, and SkyTeam – make up over 60% of the world market in recent years. There are many reasons for airlines merge and form strategic alliances, including expansion of seamless service networks, traffic feeding between partners, cost efficiency (based mainly on economies of traffic density), quality improvement, various marketing advantages (e.g., frequent flyer programs, or FFP), and the advantage of market power and cooperative pricing (Oum et al., 2000). Although in many countries where antitrust laws and active enforcement have made mergers and alliances as an instrument for market power difficult, we cannot exclude market power motive as one of the important reasons pursued by airlines through airline mergers and alliances. Similarly, with the emergence of the hub-and-spoke system following deregulation in the United States, the price charged by the hub airports has been a much-debated topic, known as the "hub premium" debate (Lee and Luengo-prado, 2005). It has been found that airline yields at concentrated hubs are substantially higher than those non-hub airports, and that the dominant airlines' yields at the concentrated airports are even higher. This implies that on the one hand, cost savings and better service could be generated by the hub-and-spoke system. On the other hand, with the ability to block entry because of a dominant presence, routes associated with hub endpoint(s) are believed to have higher fares than otherwise would be the case.

In most textbooks, market power is defined as the ability of a firm or group of firms persistently to hold price above the competitive level in a profitable way without losing so many sales that the price level is unsustainable (Motta, 2004). However,

significant market power does not seem to exist in the airline market since deregulation that relaxed market entry and exit. It is a common hypothesis that the ease or difficulty of entry into an industry has a significant impact on airline pricing. The easier entry is into an industry, the more difficult it will be for collusion to be sustained, because high prices and profits will attract new firms and break the collusion. Thus entry plays a very important role in competition analysis (Shepherd, 1997).

In the airline industry, product differentiation helps incumbents lock up some consumers by establishing a reputation through their past performance, brand names and advertising, making it difficult for new entrants to attract customers (Shepherd, 1997). In this sense, product differentiation has endogenously become an entry-detering strategy. Predatory pricing is another common pricing strategic entry barrier in the airline industry. Predatory pricing occurs when a price war is waged by incumbents against new or potential entrants. The incumbent first lowers its price to drive out the rivals and then raises it. By this means, it sacrifices a short-run loss to protect its long-run interest (Carlton and Perloff, 1999).

In the 1980s, the contestable markets theory gained its popularity and many economists believe that the airlines market is contestable (Baumol et al., 1982). As airplanes can be easily shifted to other routes, entry into a market can be largely fully reversible. In addition, compared with its large fixed costs, the airline industry faces relatively low sunk costs along particular routes. Airline markets are therefore thought to be contestable. Once a market is contestable due to free entry and exit, potential competitors will become acceptable substitutes in consumers' minds for the incumbent competitors. Whenever they see any above-normal profits in the market, potential entrants would enter and stay if they could earn sufficient revenue to cover their fixed and variable costs. Alternatively, potential entrants could follow a hit-and-run strategy, given the assumptions that they can identify consumers for their products at or below the current market price, and that existing firms are unable to change their prices quickly in response to their entry. Given such a potential threat, the incumbents' pricing behavior would be restrained by the potential entry and thereby a purely competitive outcome would result.

However, the strong assumptions associated with contestable market theory have been criticized by many economists. First, sunk costs associated with entry are most likely to exist in all markets to some extent (Spence, 1983). Even in the airline industry, for example, an airline must advertise to let passengers know before opening a new route (Stiglitz et al., 1987). Every airline market manager knows that it will take some time and effort before a new route becomes profitable. Therefore in real life, perfectly contestable markets may not exist. Second, if the entry is on a small scale with no serious threat to the incumbents, incumbents do not necessarily change their market behavior (Shepherd, 1984). They can continue to charge higher prices without losing much share of the market, or choose to accommodate the entrants. Accordingly, the contestable markets theory has gradually lost its popularity since the 1990s and market structure still plays an important role in determining an airline's pricing.

Worldwide the LCCs have expanded rapidly and led to the declining in airfares (Zhang and Lu, 2013). The LCCs now carry about 30% of the total passengers. The threat of LCCs to the legacy airlines is obvious, and can be seen not only from the fall in hub premiums, but also from the response of the incumbents (most of which have established their own LCCs). The LCCs provide low fares, high frequency and point-to-point services. In the United States, the negative effect of an LCC is present not only on the fares of the routes they are operating on, but also on the fares of adjacent competitive routes because of spillover effects (Morrison, 2001). In Australia, it has also been noticed by researchers that the emergence of LCCs not only had the apparent effect of lowering the price charged by the incumbent airlines, but also had profound effects on the incumbents' performance, labor arrangements and costs and productivity, shifting towards a socially desirable direction (Forsyth, 2003). The "Southwest effect" or "Ryanair effect" is also felt in the Asian market. In India, the market share of LCCs have been above 60% for many years, which is a remarkable achievement that makes flying more affordable for low-income consumers (Wang et al., 2018b). It has been widely agreed that the presence of LCCs represents an opportunity to develop the local economy by creating new employment and contributing to the local tourism.

Concluding Remarks

This chapter has briefly introduced the factors influencing the demand and supply in the airline market. The theories and practices of airline competition and pricing are also presented. However, it should be noted that with the increasing penetration of internet as a distribution channel, airline pricing has become more transparent, making it easier for consumers to compare prices across multiple competitors and tailor travel plans to take advantage of lower fares. Such transparency will undoubtedly make the demand for each airline more elastic. Thus there is a need for airlines to develop non-price competition strategies to retain customers and a certain degree of market power. Frequent flyer programs are an example, which is a loyalty program with an aim to maintain loyalty among those who travel frequently by rewarding them with free upgrades, free tickets, additional baggage allowances, and business lounge access (Jiang and Zhang, 2016). The FFP membership has played a strong role in airline and itinerary choice, especially for passengers with elite membership. The non-pricing competition also occurs in pre-flight, in-flight, and post-flight services, which constitutes a significant research area in the ever increasingly competitive airline market.

Introduction

The aviation industry is a fast-growing industry that doubles market size every 15 years (Airbus, 2018). This growth is largely determined by changes in government regulations and the present text describes how the privatization and deregulation of airline markets has contributed to this development.

We distinguish between (1) air services in regional markets and (2) air services between or among regional markets. Examples for air services in regional markets are air services in the United States (US), the countries of the European Union (EU), China, India, the countries of Africa, and the South East Asian Nations (ASEAN). These examples show that regional markets may be represented by a single country or by multiple countries. This observation is relevant because the deregulation of regional markets may involve national law only as in the cases of the United States, China, and India or changes in bilateral agreements between countries, which typically impose operational and ownership restriction on airlines. The system of bilateral air service agreements is based on the Chicago Convention of 1944. Over 3000 such bilateral agreements existed in 2007 (IATA, 2007).

The following describes the deregulation of the airline industry in regional markets and between or among regional markets where the latter are called “open skies agreements.” The privatization of airline companies is considered subsequently. The final part provides conclusions.

Deregulation of the Airline Industry

The world’s top three aviation markets in 2017 involved domestic flights in the United States, intra-Western European flights in the European Union, and domestic flights in China (Airbus, 2018). In the first step, this section explains deregulation efforts in these regional markets as well as, more briefly, deregulation efforts in the ASEAN countries, Africa, and India. In the second step, open skies agreements are considered.

Deregulation of Regional Airline Markets

United States

Aviation deregulation in the United States started with the Airline Deregulation Act of 1978. This act responded to the, at the time, growing concerns that industry regulation generally harms efficiency and innovation. Reforms were inspired by the contestability theory, which highlighted the possibility that potential market entry could exert competitive pressures even in the absence of *actual* firm rivalry (Bailey, 2002). The contestability theory seemed highly relevant for the airline industry because airplanes can easily be moved from market to market and were even qualified as “marginal costs with wings” by Alfred E. Kahn, who was one of the deregulators in charge (Bailey and Baumol, 1984). Furthermore, empirical studies indicated that airline businesses operate under economies of traffic density (Caves et al., 1984) and moderate economies of scale (Johnston and Ozment, 2013), which supports market concentration and highlights the role of competition by potential market entry.

Kahn (1988) concluded that the expectations that deregulation reduces fares and increases price-quality options as well as efficiencies had been fully vindicated. His findings have later been supported by the investigations of Morrison and Winston (1990). Their analysis revealed that fares were consistently lower in the past decade of deregulation than they would have been if the industry were still regulated. Later studies highlighted the negative effects of the deregulation. Goetz and Vowles (2009) found that deregulation had contributed to the financial and employment instability including the bankruptcy of airlines, reduced overall service quality, fewer flights, and higher fares to smaller places.

The Airline Deregulation Act of 1978 allowed airlines to freely reconfigure their networks. McShan and Windle (1989) proposed a method to quantify the change in hub-and-spoke routings, where passengers change aircrafts at hub airports before they can reach their final destinations. Hub-and-spoke networks have already been used before deregulation (Kanafani and Ghobrial, 1985). However, McShan and Windle (1989) found that the use of hub-and-spoke networks had increased by almost 50% between 1977 and 1984, that was, directly after deregulation.

The contestability theory had been used to explain the effects of deregulation. Baik et al. (2011) analyzed the effect of deregulation on management behavior. They found that airline managers were inclined to engage in income-increasing earnings management after deregulation.

A popular belief at the time was that economic deregulation and increased competitive pressures could lead to reduced expenditure on safety related items (Moses and Savage, 1990). By contrast, Kahn (1988) found that accident rates had been reduced by 35% in the period after deregulation. This finding was supported by Moses and Savage (1990), who found no evidence that safety performance had been impaired by deregulation. However, they emphasized that government actions are required to ensure safety in a dynamically growing aviation market.

European Union

The deregulation of the aviation industry in the European Union proceeded in three packages. These packages were implemented between 1987 and 1997 and led to a situation where every EU airline could basically access the whole EU aviation market. Button and Swann (1992) and Button (1996) asked whether the US lessons from aviation market deregulation can be transferred to the European Union. Button (1996) identified a set of differences between the US and the EU aviation markets at the time of deregulation in the European Union:

1. Charter: One can distinguish between scheduled and non-scheduled charter markets. The former serves leisure and business passengers, while the latter typically targets leisure passengers. Charter airlines were almost non-existent in the United States, while they have been common in the European Union.
2. Size: The geographical conditions in the United States and the European Union imply that average route lengths in the United States are longer than the average route lengths in the European Union, and airlines in the United States were generally bigger than their EU counterparts.
3. Ownership: US airlines were under private ownership, while government airline ownership was common in Europe.
4. Intermodal competition: High-speed rail was absent in the United States, while airline services and high-speed rail services provided comparable services for many trips in the European Union.

Despite these differences between the US and EU markets and despite their expectation that the European Union might not be as deregulated as the US markets, Berechman and de Wit (1996) still expected that the EU deregulation would ease market entry and exit, leading to more competitive choices of fares and service quality, and cause increase in hub-and-spoke operations. Their simulation models indicated that London Heathrow would become the dominant West European gateway hub, which appeared to be true.

Later studies showed that the deregulation increased both the number and frequency of routes, lowered fares, and pushed the use of hub-and-spoke airline networks in EU markets including the Central and Eastern European markets (e.g., Dobruskes, 2009; Derudder and Witlox, 2009; Burghouwt and de Wit, 2015; Jankiewicz and Huderek-Glapska, 2016; Lieshout et al., 2016). These developments were partly driven by charter operators that started adopting the low-cost business model (Burghouwt and de Wit, 2015). But, these studies also pointed out that deregulation created many new air routes operated by a single airline with potential market power, and that the main beneficiaries were the large cities and peripheral regions where deregulation helped in boosting tourist flows (Dobruskes, 2009). Lieshout et al. (2016) found that deregulation had a stronger effect on more remote regions in the United Kingdom, Spain, and Italy and that airline competition was still lagging behind in Germany, large parts of Scandinavia, France, and Spain.

China

Dating back to the Spring of 1950, China's civil aviation industry was established, and the Civil Aviation Bureau was formed after the country was newly founded in 1949 (Le, 1997). Between the 1950s and 1980s, China's economy, including civil aviation, was isolated from the rest of the world. During that time, the airline industry was considered as a semi-military organization with limited commercial operations under the leadership of the air force and the State Council (CAAC, 2002). The Civil Aviation Administration of China (CAAC), was at the top of the four-tier administration system operating civil aviation in China along with six regional civil aviation bureaus, 23 provincial civil aviation bureaus and 78 civil aviation stations (Zhang, 1998; Zhang and Chen, 2003; Zhang and Round, 2008). The CAAC was both a regulator and a manager of air transport services, and strictly regulated the industry with respect

to, for example, market entry, pricing and even passenger eligibility for air travel. Thus, a CAAC monopoly best describes the China's aviation industry prior to the 1980s (Le, 1997; Zhang, 1998; Lei and O'Connell, 2011).

The reform on civil aviation industry came later in the late 1970s echoing with the national opening-up policy. China was gradually moving from centralized planning to a market-oriented economy. The CAAC became independent from the air force. The six regional civil aviation bureaus became "half corporatized" in the sense that they were required to be financially independent (Zhang, 1998). To encourage operating efficiency and profitability, in 1987, the State Council ratified the "Report on Civil Aviation Reform Measures and Implementation." Consequently, between 1987 and 1991, six trunk airlines based in the different regional capital cities emerged. However, all the airlines, regional and trunk ones, were still tightly regulated by the CAAC and only offered standard, indistinguishable air services with little competition. The first noticeable deregulation in airfares occurred in 1997 when the CAAC encouraged airlines to adopt price discrimination in an attempt to attract more passengers. Airlines undercut the tickets prices without considering appropriately the costs in response to this policy change, which resulted in a heavy loss for the whole industry (e.g., Zhang and Round, 2008; Lei and O'Connell, 2011).

Later in 1998, the CAAC issued "The Decision to Enforce Supervision and Restore Order in the Air Market," in which it tried to regulate the airfares by limiting the discounts granted by airlines to passengers. But, the CAAC did not specify any penalties associated with violating these rules, which meant that airlines continued their "price wars." For understandable reasons, passengers also opposed any regulation on the prices (Li, 2001).

Ever since China joined the World Trade Organization in 2001 and embraced the market economy, China's civil aviation industry enjoyed a less regulated environment since 2000 with noticeable deregulation on the airline entry and exit in the domestic market. For instance, airlines could establish new routes without prior CAAC approval under certain criteria. New pricing rules were established where the government determined benchmark prices and floating bands, while airlines determined their prices within the specified ranges (Zhang et al., 2014). As a result of the deregulatory efforts, the first low-cost airlines of China, Spring Airlines, was established in Shanghai, which further increased the competitive pressure on the established full-service airlines (Fu et al., 2015; Jiang et al., 2017).

Altogether, the Chinese airline industry has been significantly deregulated; but it can still be characterized as mainly state-led rather than market-led. The low-cost carrier sector seems still under-developed (Fu et al., 2010, 2015). Further deregulation of, for example, aircraft purchase, and a transparent system of slot allocation and pilot recruitment, is recommended by researchers (Shaw et al., 2009; Fu et al., 2015; Wang et al., 2016).

ASEAN

Prior to 1995, air transport had been regulated on the basis of bilateral agreements in South East Asia (Findlay and Forsyth, 1992; Laplace and Latge-Roucolle, 2016). ASEAN took an initiative towards a more liberalized air traffic market as early as 1995 in the ASEAN leaders' summit held in Bangkok, Thailand (Forsyth et al., 2006; Hanaoka et al., 2014; Laplace and Latge-Roucolle, 2016; Tan, 2010). Over the next decade, a broader discussion about a greater economic integration across all sectors has taken place (Tan, 2010). One of the milestones for liberalization of ASEAN air traffic market was defined in November 2004 when the 10th ASEAN air transport ministers' meeting in Phnom Penh was held. In this meeting, the Action Plan for ASEAN Air Transport Integration and Liberalization 2005–15 was adopted (ASEAN, 2004). Together with the roadmap for integration of air travel sector, the action plan outlined the targets for an "open skies" regime by 2015. The idea was to establish unlimited third and fourth freedom flights for all designated points within ASEAN sub-regions by 2005 and unlimited fifth freedom rights by 2006 (Tan, 2010). Other agreements were signed in 2009 and 2010 with the goal to relax market entry and airline ownership restrictions and to establish a common policy for user charges, capacity, etc. (Hanaoka et al., 2014). However, not all targets were achieved due to failures of ratifying and accepting the agreements on a national level (Hanaoka et al., 2014). It appears that deregulation has not yet achieved its full potential in ASEAN (Findlay and Forsyth, 1992; Laplace and Latge-Roucolle, 2016; Tan, 2010, 2013).

Africa

In the late 1970s, many African governments started to negotiate open-skies agreements at all levels (Doganis, 2002). This led to the Yamoussoukro Declaration in 1988, which aimed at airline cooperation, integration, and air service liberalization in Africa. Later in 1997, the Banjul Accord was achieved to accelerate the implementation of the Yamoussoukro Declaration among six West African countries. The most fundamental move toward liberalization came with the Yamoussoukro Decision, which was signed in 1999. The Yamoussoukro Decision was supposed to progressively eliminate all non-physical barriers relating to the granting of traffic rights, particularly fifth traffic rights, aircraft capacity, tariff regulation, designation of airlines, and air freight operations (UNECA, 2002). Regions that implemented the Yamoussoukro Decision have enjoyed an increase in frequencies, air traffic, and aircraft movements as well as increased competition, which led to the improvement of the air services quality (Njoya, 2016). Yet, the implementation of Yamoussoukro Decision is incomplete because not all member countries accepted it (Njoya, 2016). Another main reason is that the institutional and legal frameworks required for the implementation of the Yamoussoukro Decision have not been put in place (Abate, 2016). The importance and benefit of greater liberalization has been widely recognized and it has therefore been suggested that African countries should work together toward a more deregulated aviation market (Abate, 2016; Mills and Membreno, 2007; Mills and Swantner, 2008; Myburgh et al., 2006; Njoya, 2016; Schlumberger, 2010; Surovitskikh and Lubbe, 2015).

India

China and India share many similarities because of the extraordinary sizes in terms of population and geography, and they both represent fast-growing economies. Their air transport sectors, however, exhibit substantial differences because private and low-cost airlines are the dominant players in India while the state-owned full-service airlines are dominant in China (Wang et al., 2018a). While India is likely to become the third largest aviation market in the world soon (after China and the United States), infrastructure development is considered the major challenge (IATA, 2018).

Open Skies Agreements Between Regional Airline Markets

The term “Open Skies” was introduced by Alfred E. Kahn to describe the objectives to be pursued after deregulating the US domestic market (Button, 2009). Winston and Yan (2015) estimated huge gains from US negotiated agreements for travelers, and they predicted further huge gains that could be achieved with additional open skies agreements. Based on a data set covering Canada’s bilateral service export and import data, Oum et al. (2019) found that the effect of open skies agreements on service trade, however, can be positive or negative. No strong link between open skies and tourist flows was found by Dobruszkes et al. (2016).

The following discusses specific open skies agreements in more detail.

Europe–United States

The European Union–United States open skies initiative can be considered as one of the most significant international airline deregulation efforts worldwide (Button, 2009). From 1992 onwards, a series of bilateral open skies agreements between the EU countries and the United States were established. These agreements removed restriction on fares and service levels and allowed airlines to fly between countries if the flight originates or terminates in the airline’s home country (fifth airline freedom). They were replaced by a new transatlantic agreement in 2007 (Hunnicutt, 2010).

The short-term effects of the new transatlantic agreement were changes in airline service offerings, particularly at London Heathrow airport (Pitfield, 2009). In a later study, Cosmas et al. (2010) found that these changes involved both increase in service levels for some countries and reductions in service levels for other countries. That the new (de)regulatory environment might have brought service levels down was further confirmed by the findings of Morandi et al. (2014). According to their study, direct transatlantic connections and served airport pairs have decreased after the signing of the new agreement. Zhang et al. (2018) added to these results with their finding that the US airlines are more likely to take advantage of the possibilities provided by open skies agreements. One explanation is provided by Morrison and de Wit (2019), whose study revealed that financial aid and policies have advantaged US airlines. They expressed their concerns that markets have been made more unleveled during the era of open skies agreements.

Other Open Skies Agreements

The European Union has concluded horizontal agreements where EU carriers can operate routes between any EU country and a third country with several African countries. These include the members of the West African Economic and Monetary Union, Morocco, Cape Verde, and Tunisia (Njoya et al., 2018). The European Union–Morocco open skies agreement, which was signed in December 2006, has been studied by Bernardo and Fageda (2017). Their econometric analysis revealed a 20%–35% increase in the number of seats offered on pre-existing routes and a notable increase in the number of new routes offered. These results are in line with Njoya et al.’s (2018) results. They found that the horizontal agreements between the European Union and African countries substantially increased service levels and lowered fares.

The China–US market has been studied by Lei et al. (2016). In 2004 and 2007, China and the United States negotiated air service arrangement protocols which had profound impacts on the China–US market. These protocols intensified competition, improved the Chinese airlines’ operating and financial performance and strongly increased traffic growth.

A recent study by Wang et al. (2018b) considered deregulation between China and Central-Asian countries in the context of the Belt and Road initiative of the Chinese government. The investigation suggested that great benefits could be achieved if more liberal aviation policies such as those proposed by the Belt and Road initiative of the Chinese government were introduced. The analysis suggested that if the Central Asia–China markets were regulated and operated in a similar way to the routes between Central Asia and other states, the probability of having aviation services between cities in China and Central Asia would increase substantially, with more direct flights to a larger number of Chinese cities such as Xiamen, Shenzhen, Hangzhou, Qingdao, Chengdu, and Kunming.

Airline Privatization

A change from public to private firm ownership can serve efficiency, financing, and distributive objectives (Vickers and Yarrow, 1991). These objectives are interdependent in the sense that the effect of privatization on the efficiency of firms relative to a situation with public ownership can depend on whether the firms’ environments are competitive or monopolistic. More specifically, the efficiency effects of privatization may be limited in a competitive environment (Vickers and Yarrow, 1991). The deregulation of aviation markets coincided with airline privatizations. Note that private ownership typically involves local ownerships because trans-border airline investment is often limited by the constraints embedded in the national airline establishment

regimes (Walulik, 2016). The following airline privatization studies and cases provide evidence for the effects of deregulation and airline privatization on aviation markets.

By 2016, there were around 27% and 40% of airlines (excluding Low-cost airlines) around the world that are completely state-owned and completely privatized, respectively. While the rest of airlines are mix-owned by the governments and private investors. Continent-wise, the number varies dramatically with the lowest 5.6% of completely privatized airlines in Oceania and Pacific Islands regions, and highest 69.6% of completely privatized airlines in North America, where all US airlines are completely privatized, while in Canada, a couple of airlines belong to, for example, First Nations. In Latin America and the Caribbean, the share of fully privatized airlines is 46.5%, in Europe it is 45.5%, Asia 39.5%, Middle East (including North Africa) 25% and Africa (excluding North Africa) 22.2%. This shows that a large share of the airlines worldwide is still completely or partly owned by the governments (Czerny and Lang, in press).

Several studies have analyzed the effects of airline privatization on their performance. Al-Jazzad (1999) found an overall positive evidence of private airline ownership on performance in the sense of growth in sales and net-income, total assets, capital expenditures, and dividends after privatization. Interestingly, the findings further indicated an increase in employment after privatization. Chow (2010) showed that non-state-owned airlines performed better than their state-owned counterparts. The study by Backx et al. (2002) covered mixed ownership structures in their analysis. They found that airlines with mixed ownership tend to perform better than publicly owned airlines, but worse than privately owned airlines. On the contrary, Chen et al. (2017) focused on the Chinese market and found that Chinese airlines are better off with strong privatization or majority of state ownership than with mixed ownership. The findings are consistent with Wei and Varela (2003), Shirai (2004), Wei et al. (2005), Tian and Estrin (2008), and Ng et al. (2009), which all supported that businesses can benefit from either strong state ownership or strong privatization. However, no significant negative or positive effects of public ownership have been found by Sjögren and Söderberg (2011).

The following considers specific privatization cases. Air Canada has been partly privatized in 1988 and fully privatized in 1989. Gillen et al. (1989) found that the public ownership of Air Canada has historically resulted in a substantial loss of productive efficiency due to an overexpansion of its capital. Eckel et al. (1997) analyzed the effect of privatization on the performance of British Airways. They found that airfares fell in the markets served by British Airways and stock prices of US rivals fell upon British Airways' privatization. Both effects indicated the possible pro-competitive effects and efficiency gains of airline privatization. The case of Argentina showed that the selling of publicly owned shares in airlines to private owners can be complicated. While many bids existed for the national flag airline Aerolineas Argentinas at the beginning of the process, only one bidder remained in the end, and there were allegations about corruption (Saba and Manzetti, 1997). The privatization of Kenya Airways in 1996 helped avert liquidation of the company and is considered a success story because it has helped the management to focus on commercial goals and objectives (Debra and Toroitch, 2005).

Conclusions

The historic development of the airlines' regulatory environments and ownerships across countries, regions, and continents has been described in this chapter. It was shown that deregulation in the air transport market has become a mainstream development, and that deregulation has changed aviation markets in many positive ways. Deregulation generally led to stronger competition, reduced fares, increased flight frequencies, more connections, and increased passenger numbers. This strongly indicates that deregulation is beneficial to the aviation industry and society and thus desirable, which is a conclusion that is well in line with those from other researchers (e.g., Oum et al., 2010).

Deregulation is still far from completion. In China, the market is still characterized as state-led rather than market-led. The restrictions on low-cost airlines in China result in fewer low-cost airlines and softened competition. In ASEAN and Africa, many promising plans for deregulating the aviation market have not been realized yet.

The airlines' privatization development around the world has been briefly described as well. Many studies showed that public airline ownership can be associated with major financial losses. Private ownership helped avoid such losses by improving efficiency and increasing revenues. However, a large share of today's airlines is still completely or partly government owned.

An Introduction to Price Discrimination

Price discrimination is a business term referring to the charging different prices to different customers, even though they are purchasing the same product produced with the same marginal cost. The concept of price discrimination was first proposed by a French economist, Jules Dupuit in 1840s, who suggested that some transportation and utility firm could benefit from engaging in the price discrimination strategy (Ekelund, 1970). It is believed that a monopoly firm's profit can be enlarged if the market can be segmented to allow the buyers to pay a price close to what they can afford (Gifford and Kudrle, 2008).

It is well known that a firm's ability to price discrimination depends on three conditions (Varian, 1989): the possession of a certain degree of market power; the ability to segment the market; the ability to stop the resale of the product or service from one buyer segment to another. The practice of price discrimination is one of the causes of price variation in the airline industry. There are three types of price discrimination: first degree, second degree, and third degree.

First-degree price discrimination is called perfect price discrimination, which charges each consumer a price equal to the consumer's willingness to pay. Although consumer surplus is completely eliminated under first-degree price discrimination, it is economically efficient and the production is at the point where marginal cost equals marginal benefit. However, in reality, this type of price discrimination is unlikely to happen because a firm usually does not have the ability to determine a consumer's reservation price. Therefore, no airline can practice first-degree price discrimination.

Second-degree price discrimination is the practice of charging consumers different prices for different quantities of a homogeneous product consumed. This type of discrimination allows the firm to take part, but not the entire consumer surplus by offering a few, well-defined pricing categories. A frequent flyer program may fall within this type of price discrimination as the points awarded to the passengers can be used later, which is a special kind of discount and consumers do not need to pay for the points at the time of purchasing the ticket.

Third-degree price discrimination refers to the charge of different prices to different consumer groups such as male and female, children and adults. That is, special discounts are offered to some groups and thus each group pays a different price for consuming the same product or service. This type of price discrimination allows the firm to expand its client base, as some consumer groups may not buy the product or service without the discount. Many airlines offer corporate travel programs to companies and give cheaper contract prices, which is a practice of third-degree price discrimination.

Third-degree price discrimination is most commonly used by the airline industry. Airlines divide consumers into different groups based on a set of characteristics and charge higher prices to those with the most inelastic demand. A typical example is to make a distinction between time-sensitive (mainly business travelers) and non-time-sensitive passengers (mainly leisure travelers), as well as between point-to-point passengers and connecting passengers. Generally, time-sensitive travelers prefer faster connections and place a lot of value on flight punctuality and frequency of service. They usually do not book their flights in advance. Their tickets need to be transferable from one flight to another in the event of changes in travel plans at short notice. As their company usually pays for their tickets, this group of passengers often buys less restricted tickets at a higher price. In contrast, non-time-sensitive travelers are interested in obtaining the lowest fares and are willing to accept longer travel times and more restrictions on the use of their tickets, for example, not refundable, not endorsable, no route and date/flight change, etc. In practice, business passengers can be identified by their inability to book in advance and by buying tickets with fewer restrictions.

Interestingly, some researchers argue that airline pricing falls somewhere between first- and second-degree price discrimination because of the use of computer reservation system (CRS) (see, e.g., Kons, 1999). The reason is that although it is impractical to obtain all the potential customers' reservation prices, which makes first-degree impossible, the creation of a large number of prices possible by the CRS allows the airlines to snatch more consumer surplus than second-degree discrimination offers.

Overall, it is generally agreed that price discrimination has helped lower the average fare these days, although it may raise the fare for some consumer groups (Vasigh et al., 2018). Compared with the single pricing strategy that may drive some price-sensitive passengers out of the airline market, price discrimination can increase load factors and economic efficiency due to the greater output produced.

New Business Model Enhances Price Discrimination: A Case of the Australian Airline Market

Qantas and Virgin have reported bumper profits in the first half of the 2017–18 financial year. The record profits for Qantas mainly came from the domestic market—Qantas and Jetstar’s domestic business recorded the highest ever first-half underlying EBIT of \$ 652 million (<https://www.qantasnewsroom.com.au/media-releases/qantas-delivers-record-first-half-profit-invests-in-aircraft-and-training/>). Virgin Australia also attributes its 142% growth in underlying profits to the strong domestic demand from business and leisure flyers (<https://www.businessinsider.com.au/virgin-australia-has-returned-to-profit-2018-2>). Strong demand and cost control are two frequently mentioned factors for their success in the domestic market. However, another factor that is less mentioned is the airline-within-airline (AinA) business model adopted by Australian major airlines (Zhang et al., 2017, 2018). This business model is another example that promotes price discrimination in the airline industry.

The AinA strategy was largely a failure in the United States and Europe, as most low-cost subsidiaries of the full-service carriers did not achieve sufficient low costs to compete against the standalone low-cost carriers (Morrell, 2005). As a result, some of the US carriers, such as American Airlines sought to segment their cabin seating and offer a basic economy seating class to those looking for cheaper prices.

Australia’s domestic airline market today is a classical duopoly (Ma et al., 2019). Qantas has successfully implemented the AinA strategy and used Jetstar as a fighting brand against other low-cost carriers in maintaining the group’s total domestic market share at around 65% in the last decade. Virgin has also successfully used this model to snatch a substantial share of Qantas’ business and corporate passengers in the last few years, and at the same time continued to use Tiger to target the leisure market.

The increasing use of Internet for airline ticket distribution has made it easier for consumers to compare prices across multiple competitors. This has limited the airlines’ ability to practice price discrimination. Price discrimination has been a common practice in the airline industry used to transfer consumer surplus to airlines’ own profits through charging different prices to different consumer groups based on the knowledge of consumers’ willingness to pay.

The AinA strategy has allowed extensive capture of consumer surplus of segmented customer groups to a maximum extent. In August 2017, of Australia’s top 144 domestic route markets in terms of passenger traffic volume (each direction of a route was counted as a separate market), Qantas and Jetstar were simultaneously present in 95 markets while Virgin and Tiger in 75 markets. The number of markets where all the four carriers were present was 71 (Ma et al., 2019).

In fact, the four carriers were simultaneously providing services on most of the heavily traveled and profitable domestic routes where each airline group can exploit consumer surplus of both business and leisure passengers. Consumers in these markets are sufficiently heterogeneous in term of their travel demand. The AinA model ensures that a variety of products are provided on these routes to meet consumers’ demand, which allows the two airline groups to maximize the potential of their revenue.

The capture and transfer of consumer surplus from passengers of each segment to airlines could substantially offset the loss resulting from the price war episodes. In addition, in many cases, price wars are only restricted to the product of a certain market segment. The prices for other segments may have little fluctuations. This is confirmed from the charts of the Domestic Air Fare Indexes published by the Department of Infrastructure, Regional Development and Cities, Australian Federal Government, in which we can see that only the best discount fares, exhibit wide fluctuations (https://bitre.gov.au/statistics/aviation/air_fares.aspx).

Price discrimination can increase total social welfare as it allows more products to be produced to a greater number of consumers, some of whom may otherwise not have access to these products. As long as consumers continue to regard Qantas (and Virgin to a less extent probably) as a premium brand and as long as it can successfully maintain such image, most of them will happily transfer part of their consumer surplus to the carrier as profits.

A Short History of Yield Management

Yield management is a pricing strategy that has been adopted by the air transport industry for decades. It is a strategy used to maximize profit by charging the consumer of different demand at a different price. This strategy is mainly popular because airline products, namely, transport services to both passenger and cargo are perishable, which cannot be stored, saved, returned, and resold after the departure of the flight (Nairn, 2005). Yield management helps the carriers to achieve high load factors to ensure high yields.

Yield management related program was first introduced by British Overseas Airways Corporation (BOAC) in the 1960s after the new jet airliner B707s was introduced and resulted in a substantial increase in the capacity that the airline could offer (Easton, 1959). Compared with the aircraft DC-7C used by BOAC, the payload of B707 was almost five times higher. This led to the launching of the excursion fare discount program known as “Early Bird.” The discount was first offered to passengers traveling between the United Kingdom and the Caribbean and later made available on other routes (Cole, 2005). The “Early Bird” discount came with some conditions. For example, passengers must book their seats three months in advance. They might be required to have a minimum stay of fourteen days at the destination.

Yield management has become popular in the United States since 1980s after the airline industry was deregulated. Throughout the period from the 1940s to 1970s, the US airline market was controlled and regulated by the Civil Aeronautics Board (CAB), which exercised its authority over entry and exit, pricing, capacity, frequency, and so on. The greatest event in the airline industry was the passage of the Airline Deregulation Act (ADA) in the United States in 1978. This led to a series of liberalizations in fares, services, and entry and exit to and from this industry across the world (Zhang and Round, 2008). Carriers were allowed to adjust fares, to service new markets, and to enter or exit as long as they met certain basic requirements.

Following the air deregulation act in 1978, many new airlines entered the market. The intensely competitive environment forced airlines to explore new strategies to cope with market change (Law et al., 2018). For example, People Express Airlines based in New York launched its operation in 1981. The airline adopted the low-cost business model and soon became a serious threat to the giant airlines including American Airlines and United Airlines. The newcomer forced both American Airlines and United Airlines matches the People Express Airlines airfare. However, matching fare with the low-cost competitors was not a long-term strategy given the different cost structure between the full service and low-cost airlines. To obtain a balance between price and payload, American Airlines developed a yield management system to compete with other carriers with the aid of CRS (Smith et al., 1992; Cross, 1995).

Airline distribution for many years has been synonymous with the CRS, later termed the Global Distribution System (GDS). The GDS provides virtual real-time connectivity between thousands of suppliers of travel inventory (airlines, hotels, car rental, tour operators, cruise lines, etc.) and hundreds of thousands of retail sellers of travel products (Sismanidou et al., 2009). The system has significantly improved airlines efficiency in attracting and retaining customers and driving sales through travel agents. These gave American Airlines numerous consumer behavior data, which allowed the airline to develop a sophisticated yield management program to attract both the high yield and low yield passengers (Sabre, 2019). In contrast, those airlines operating with a low-cost model with simple single fare structure were unable to react to this strategy. As a result, some of the small and low-cost airlines were driven out of business. Other airlines followed suit and applied the yield management strategy.

Conditions for the Application of Yield Management

Yield management is a technique used by many industries, particularly in those with capacity constraint (Kimes, 1989). The objective of applying yield management is to maximize revenue with limited resources. Air transport companies use yield management to increase their revenue for each flight by predicting the travel demand of different travelers segments between origin and destination and charge each segment with an optimal price. Airline products have the following characteristics that make them most suitable for the application of yield management: each aircraft has fixed capacity; the products are perishable and cannot be stored for the next flight; the passenger groups can be segmented into different sub-groups that allow airlines to charge different prices accordingly; passenger demand is subject to frequent fluctuations; the products can be sold in advance; the marginal cost is relatively low as compared with the fixed cost (Wirtz et al., 2003).

Successfully applying the yield management technique is not an easy task. Airlines are required to divide the customers into smaller segments and offer them the most suitable and wanted products. Given that contemporary business environment changes frequently and rapidly, airlines need to collect customers' purchasing behavior data, based on which the airline can monitor the market, change the fare and control the seat inventory (Akerkar, 2014). The objective is to ensure that not all seats are sold at a low price to reduce the airline revenue, while at the same time the seats are not sold at an expensive price that steers passengers away to the competitors, leading to aircraft departing with empty seats. An effective application of yield management requires the following conditions: an effective constraint that prohibits high yield passengers to buy low fares; a mechanism to allocate seats to maximize revenue in the face of demand fluctuations; and a reliable prediction of demand, no-shows, overbooking, etc. (Ozer and Phillips, 2012; Wensveen, 2015).

To ensure that the right price is charged based on the customers' demand; airlines have created multiple booking codes in a cabin class. To differentiate each booking code, different restrictions are set to prevent the high yield customers from buying low fares. In general, the lower fare class, the more limitations. Common restrictions (also called fences) include (Wensveen, 2015; Vasigh et al., 2018):

- Advance purchase requirement
- Restrictions on earning frequent flyer points
- Restrictions on departure days and times
- Round-trip requirement
- Minimum and maximum stays
- Flight change and refund penalties

Yield Management Methods

To maximize the profit, an airline needs to identify the amount of inventory available at each fare bucket. Fare buckets are closely connected, known as serial nesting (Vasigh et al., 2018). When a seat was sold from one fare bucket, the amount of inventory remaining in other buckets may be affected. For example, when a seat in the higher fare bucket was sold, a seat from the lower fare bucket will be reduced. Therefore, the key of airline yield management is about the seat inventory control. That is, optimally allocating the fixed number of seats to the demand before a flight departs.

The leg-based yield management system is common in the airline industry. In the single-leg seat inventory control, the booking system evaluates a booking request by one segment of flight without considering the complete itinerary of the travelers. In other words, the system shows the same availability to all travelers regardless of a single-leg or multiple-leg journey in the passengers' itinerary (Skugge, 2002).

Following air transport liberalization, many airlines have adopted the hub-and-spoke system. Today, the majority of travelers' itinerary consists of multiple flights, as most routing required the travelers to transit at a hub airport. This is facilitated by the proliferation of airline alliances and code-share agreements, which have increased the complexity of the traditional yield management system. Network seat inventory control is thus called for and an airline's network is optimized simultaneously.

The Origin and Destination (O&D) yield management system provides a solution for network seat inventory control to carriers when itineraries involve connecting and code-sharing flight legs (Millward, 2014). The O&D yield management forecast the travel volume by city pair based on the passengers' complete itinerary including the inbound and outbound connections, which allows the airline to obtain accurate demand data and implement the right pricing strategies (Skugge, 2002). Various mathematical programming models have been developed to realize the network seat inventory control (Williamson, 1992).

Upgrade bidding and airport upsell have become useful yield management tools for some airlines to maximize profits. This strategy is useful to resolve problems when there are forecast errors between supply and demand (Gallego and Stefanescu, 2009). The airline offers passengers in the lower cabin to entering an auction exercise for upgrading to premium seating by additional payment. The customers are free to offer their bidding price (Rosen, 2018). Closer to the departure date, when premium seats are still available, the airlines will issue the upgrade confirmation to those passengers who offer the highest bid. Airport up sell is another strategy similar to the upgrade-bidding program. Some airlines offer to up sell deal to passengers to upgrade to higher service cabin on the departure day with a charge at the airport check-in counter (<https://atwonline.com/blog/airlines-need-master-art-upsell>). These strategies allowed the airline to earn additional last minute earning to further maximize their profits.

Big Data Analytics, Artificial Intelligence, and Yield Management

Traditional yield management adopted by airlines for decades relied on the historical data collected by the CRS. Modern technology has changed the shape of yield management, which allows airlines to gather data before customers purchase tickets. Big data and artificial intelligence are two technologies that are closely linked and can revolutionize the traditional yield management system. Big data refer to the raw data or inputs that are uncleansed and unstructured, while artificial intelligence is the output and actions taken to resolve the issues. The development of artificial intelligence into yield management system gives the airlines a large volume of useful data of customer demand, which makes it possible for the airlines to offer a fare that is closer to the customers' demand (Corominas, 2016). The big-data based artificial intelligence system collects data from the passenger's flight search history over the internet to examine the demand for flights. Based on the customers' browsing pattern, the artificial intelligence system tracks the changing volume of search requests from the airline website or other search engines. The artificial intelligence allows the airlines to make prompt changes to the airfare, if needed (Hinke, 2018). In particular, the artificial intelligence system generates customer-centric offers and develops personalized pricing strategies to meet the needs of consumers (<https://www.triometric.net/the-ai-opportunity-in-revenue-management/>). The new technology is the key for the modern era airlines to maximize profits and succeed in the rapidly changing business environment.

Introduction

Many of the world's railways were originally built by private companies. Whilst there were often competing main lines between the major centers, they had a degree of monopoly, and—where it existed—the competition was typically between two or at the most three companies. Since they had at the time a very strong market position in both passenger and freight transport, detailed regulation was seen as necessary, including controls on maximum fares and charges and imposition of common carrier obligations, including controls on the ability to withdraw services and close lines.

Over the years, in much of the world, the rail system became publicly owned with the pattern of a single, vertically integrated public monopoly taking control. Often regulation by a separate regulatory body continued for some time, but gradually the fact that passenger services were largely operated under public service obligations and that freight was struggling with intense competition from road made this redundant and it was removed. In North America, on the other hand, the rail system remained primarily privately owned, vertically integrated, competing over parallel routes and concentrated on freight. Because of the unprofitability of the industry, most controls on freight rates and services were removed, most notably in the US by the Staggers Act of 1980. This is considered in the next section.

In Europe, reform went in a different direction. Up until 1999, the European Commission had accepted that railways would remain publicly owned vertically integrated monopolies. Legislation had concentrated on giving them management autonomy and trying to create a level playing field with other modes of transport by relieving them of inherited non-commercial obligations. But there was much dissatisfaction with the performance of this system on behalf of both the European Commission and member states. In the 20 years from 1970 to 1990, rail freight market share in Europe went down from 20.1% to 11.0%, and passenger market share down from 10.2% to 6.6%, whilst subsidies rose. Obviously this loss of market share was due to many factors, some outside the control of the railways – for instance rising car ownership, improvements in road infrastructure and decline of heavy industry – but railways were doing poorly even in markets such as international freight which being longer distance ought to have provided more favorable prospects for rail. Thus in 1991 came the first steps in a radical shift in policy in favor of separating train services from the infrastructure, which was recognized as the true natural monopoly, and introducing competition into the operation of services. The next two sections discuss this separately in the case of freight transport and passenger.

This structure imposed a new need for regulation, partly to ensure that entry conditions did not discriminate in favor of the incumbent, but also to oversee the performance of the new monopoly infrastructure managers. This issue is discussed in section “Europe—the new regulatory bodies”.

Finally in section “Reform in other countries” we review briefly the reform of the rail systems in other parts of the world, including the major rail systems of India, China, Russia and Japan, and the role that regulation or deregulation has played in them before reaching our conclusions.

The US Staggers Act

Until the Staggers Act of 1980, the US had strict regulation of railway tariffs and services. Railways had to carry traffic at the published tariff; individually negotiated tariffs were not permitted. Unprofitable services could not be discontinued and lines closed; these had to be cross-subsidized out of the profits on the healthier traffic. This included cross subsidy of passenger services until 1970, when AMTRAK was set up as a separate government owned passenger operator, operating extensively over the track of the freight companies on a marginal cost basis. It should be said that the pattern of tight regulation of rates and continued cross subsidy of unprofitable traffic from profitable has been a common form of rail regulation, and still continues in India and China. But with the growth of road competition it has become less and less sustainable. Firstly, rail experiences a marginal cost well below average cost,

so average cost pricing may lose much traffic to road which is willing to pay its marginal cost on rail. It is necessary to price differentiate according to the willingness to pay of individual customers in order to recover as much as possible of total cost whilst retaining such traffic. For freight traffic, this is most thoroughly achieved by individually negotiated tariffs. Moreover such tariffs may impose conditions such as investment in terminals or provision of minimum volumes of traffic so that more efficient ways of operating (for instance in full train loads) may be adopted. Secondly, even with price discrimination, rail has often been unable to make sufficient profits to continue cross-subsidy.

In the US, by the 1960s the rail industry was becoming increasingly unprofitable, and even the removal of the requirement to cross-subsidize passenger services could not reverse this trend. Following the bankruptcy of Penn Central, the government realized radical change was needed, and the Staggers Act of 1980 largely swept away the existing regulation. With the ability to negotiate individual contracts, average revenue per ton kilometer halved over the succeeding two decades, but costs fell even further (Winston, 2006). Whilst some routes were abandoned, the availability of road haulage meant that this was not generally a big problem. Indeed, although some residual regulatory power to deal with possible monopolistic pricing policies by US railroads was retained, it was generally considered that the continued existence of parallel competing railroads, each with their own track, the strong competitiveness of road and in some cases water transport, and the competition from competing sources of supply meant that the monopoly power of the railroad industry now was weak. However, there has been a substantial decline in the number of separate US railways in recent years and presumably therefore a decline in intra modal competition. To a degree, this has been mitigated by requirements for the granting of running rights to other operators as a condition of merger, and there have also been voluntary running rights agreements on a purely commercial basis. Thus whilst the US system is fundamentally a vertically integrated network, around a quarter of its length is used by more than one train operator.

Europe—Freight Traffic

In Europe, as noted above, the situation was very different. Each country had a monopoly operator, and international traffic, which was always important in Europe, was handled by the operator simply handing the traffic over to the rail company of neighboring country at the border. The result was that international rail freight tended to be slow and unreliable.

In 1999, the European Commission issued a new railway policy document advocating separation of infrastructure from operations and the introduction of competition into operation of train services. The first step in this direction was introduced by way of Directive 91/990 in 1991. This required at least accounting separation of infrastructure from operations and passenger from freight, and the opening for new entry of some types of international freight. In subsequent directives, separation was to be taken further to provide independent management of infrastructure from operations. Many countries achieved this by completely separating infrastructure into a separate company or agency, although it and the major operator (at least of passenger services) remained publicly owned. (Drew and Ludewig, 2011). Others, notably Germany, Italy, Austria and later France, kept infrastructure and the main train operator as separate subsidiaries of a holding company. Only in Britain were both the infrastructure manager and all train operators privatized, although in Britain the privatized infrastructure manager became bankrupt and reverted to the public sector.

By 2007, complete freedom of entry into both domestic and international freight services for an operator based in any EU country which had the necessary license, which was to be granted solely on terms of safety of operations, was legally required. As well as non-discriminatory access to the main rail infrastructure—the tracks—entrants were given non-discriminatory rights of access to other facilities including terminals, marshalling yards and maintenance depots. New entry was slow, but by 2016 entrants had on average 39% of the European freight market (European Commission, 2019).

Some countries also sold their railway freight businesses. Indeed, there is strong evidence that horizontal separation (separation of passenger and freight operations) has led to lower costs. Invariably, these freight businesses passed into the hands of foreign railway companies. Thus, DB (German Railways) now owns the incumbent freight companies of Britain, Netherlands and Denmark, and OBB (Austrian Railways) that of Hungary. Only in Britain was there a decision to divide the incumbent into two (or more) separate companies and sell them separately to create more competition. Thus in Britain the container company Freightliner was sold separately, and in due course also entered the heavy haul market, whilst the bulk haulage company (now DB Cargo UK) entered the container market, providing competition for all types of traffic.

In general, it is considered that there is sufficient competition either within the rail sector or with other modes for rail freight now to operate without any regulation other than on safety grounds. The introduction of competition in the rail freight sector seems to have been largely successful, with the choice of operator leading to improved services and lower costs, although there is no clear evidence of an impact on mode split. An important issue here is that charging of road hauliers for the costs they impose, including externalities, whilst permitted under EU law is not required. Where road hauliers are not charged full marginal social cost, there is provision for offsetting grants to contribute to rail track access charges for competing rail services, and some countries—including Britain—make explicit use of this provision.

Europe—Passenger Traffic

Following the 1991 reforms, some countries took the opportunity to introduce competition into the passenger sector as well as freight, even before this was required by European Legislation (Nash et al., 2016). Thus, over the period 1994-97 Britain placed

virtually all its passenger services in 25 passenger franchises and let them to private companies by competitive tender (the state owned operator, British Rail, was not allowed to bid and thus disappeared as a train operating company). Sweden had already introduced competitive tendering for subsidized services and in 2010 began opening access for commercial services. Germany introduced open access for commercial services in 1994 and permitted states, who were responsible for all rail subsidies (though with funding from the federal government) to choose between competitive tendering and direct awards for subsidized rail services. These three countries are the only ones where new entrants hold a substantial share of the rail passenger market. Other countries, including the Netherlands and Denmark, practice a small amount of competitive tendering for noncore routes. Generally, the results of competitive tendering have been positive, with lower subsidies and better services.

Several other countries have seen some entry into the commercial passenger market. But it is Italy and the Czech Republic that offer the most dramatic examples. In Italy, NTV entered the market, offering a competing network of high-speed trains duplicating those of the incumbent, Trenitalia. In the Czech Republic, two entrants, Regiojet and Leo Express, entered the market competing with the incumbent Czech Railways on the most important route, gradually extending to the second key route and some international connections.

In general, open access competition has seen improvements in services and lower fares. But it has also led to duplication of services taking up scarce track capacity, and likely loss of revenue by incumbents meaning either increased subsidies, increased fares or cuts in services elsewhere. Many of the benefits of competition (without the associated problems) could potentially also be achieved by competitive tendering for franchises for commercial services, but Britain is the only country so far to have adopted this approach. However, in Britain the reforms have been accompanied by a significant increase in costs. In part this has been blamed on the fact that vertical separation has meant that the infrastructure manager and train operators each try to optimize their own costs rather than the system as a whole (although Britain does have the most complex system of track access charges and performance regimes in Europe to try to give all parties the correct incentives). There is wider evidence that vertical separation may increase costs on densely used systems (Mizutani et al., 2015), perhaps justifying placing infrastructure and the main train operator in the same holding company, which may then play a coordinating role, or implementing other measures such as alliances (agreements to work together on specific issues, with or without sharing revenues and costs) to try to overcome the misalignment of incentives. But the cost increase may also be partly the result of the way franchising was undertaken in Britain, with the existing services placed in a number of relatively large companies, control of which would be taken by the winner of the franchise competition. Thus there was no scope for new franchisees to bring their own workforce, wages and conditions. There is some evidence that the very small open-access operators have lower costs even than the winners of franchise competitions, although it is not clear whether this cost advantage would survive were open access competition to expand.

Legislation has now been passed that will completely open the rail passenger market for competition across the EU. Open entry for passenger services was first required on international routes in 2010 though with some protection for domestic services on the domestic parts of international routes. Under the 4th railway package, competition will be allowed for all commercial services from December 2019 and by means of competitive tendering for services operated under public service obligations by 2023. Again there are some exemptions; direct awards are still permitted if they can be justified to a relevant independent body such as the rail regulator, and open access for commercial services may be limited if it would adversely affect the financial stability of services run under a public service contracts. Moreover some countries have used the direct award of long (e.g. 10 year) franchises in the run up to liberalization to postpone the introduction of competitive tendering.

Europe—The New Regulatory Bodies

Whilst in North America, following the success of the Staggers Act, the general view was that regulation of the rail sector should be minimized, in Europe the reforms actually led to a need to strengthen regulation (Benedetto et al., 2017). The key reason for this difference was that North America continued to have competing vertically integrated railways, whilst in Europe competition took the form of competing train operators running over the same tracks, retaining a monopoly infrastructure manager. In most cases, the state owned the largest train operator as well as the infrastructure manager, and there were fears of discrimination favoring this train operator (obviously these fears were strengthened in those cases where the two were subsidiaries of the same holding company). Moreover, European governments were not willing to allow competition from other modes to determine what passenger services were provided, seeing political as well as economic, social and environmental reasons to subsidize unprofitable passenger services even when competing modes took much of their traffic. So the disciplinary power of inter modal competition in the passenger market was blunted and thus also the impact of this on the infrastructure manager (this is true in North America as well, but the importance of passenger traffic is very much less than in Europe). As a result, the new legislation required there to be an independent regulator, who should at least ensure that European legislation on issues such as track access charges was implemented and that non-discriminatory access (both in terms of prices and the quality of service offered to operators) was available for all. In addition, the regulator could be given the task of ensuring the efficiency of the infrastructure manager by using benchmarking to estimate efficient costs and ensuring prices were based on these (alternatively the efficiency of the infrastructure manager could be dealt with as part of a multi annual contract determining the infrastructure capability to be delivered and the funding to be made available for it between the infrastructure manager and the state).

In practice few countries made this part of the function of the regulator and only in Britain has the regulator undertaken extensive benchmarking studies as the basis for the approved prices. International benchmarking and regional benchmarking (comparing

different regions of the infrastructure manager against others) has been used, adopting statistical techniques as used by utility regulators, as well as bottom-up engineering studies. A key challenge has been addressing heterogeneity and obtaining good quality data. Further, given that the regulator's efficiency determination would impact on the infrastructure manager's funding and in turn on the call on public funds, transparent mechanisms had to be introduced to give the government an opportunity to de-specify outputs to fit within the available public subsidy.

When infrastructure is separated from operations track access charges become an essential part of the mechanism giving train operators the right incentives regarding how many trains to run, when and where to run them and what sort of rolling stock to use. In general, rail systems are subject to economies of traffic density, so charges that reflect marginal cost will not recover anything like total cost. On the other hand, prices that have significant mark-ups recover total cost but will discourage some traffic from using rail even when willing to pay marginal cost.

EU legislation requires infrastructure charges to be based on marginal cost (basically the cost of wear and tear on the track, plus congestion or scarcity where capacity is less than demand and environmental costs provided that the overall level of rail track access charges is not raised by them unless these costs are charged to other modes as well) but permits non-discriminatory mark ups where necessary to recover those costs not met by the state (Nash et al., 2018). These mark ups may be based on Ramsey pricing principles—in other words higher mark ups for traffic less sensitive to price—but may not vary between train operators for the same traffic. In practice, track access charges vary greatly between countries, with some countries such as Germany and France seeking to recover total cost (albeit with the state directly paying for investment in the case of Germany) and others (such as Sweden and Britain) basing them on marginal cost with the remaining costs being paid by the state (in Britain, there is a fixed charge paid by passenger franchisees but since this simply makes an equal reduction in the bids of those competing for franchises it may be viewed as the equivalent of being paid by the state). Importantly, there are also great variations in the extent to which charges vary by type of rolling stock and route (such variation is necessary if charges are to reflect accurately the costs caused by a particular train and therefore to give the correct incentives in terms of what trains to run and what types of rolling stock to use or for manufacturers to develop).

Finally, the level of access charges can also have an impact on the ability of competition to develop in the market, and this has been a policy issue in a number of EU countries.

Reform in Other Countries

In general no other countries have followed the European model, although some South American countries have implemented franchising for freight as well as passenger services, using long vertically integrated franchises (Thompson and Kohon, 2012), and Australia has a degree of vertical separation of infrastructure from operations, with open access for freight and some competitive tendering for passenger services. But the world's largest railway companies – those of Russia, China and India – have remained essentially vertically integrated monopolies with cross-subsidy of passenger traffic by freight. Indeed, these railways are still at the earlier stage of European reform; until relatively recently all were still run by a Ministry of Railways (Indian Railways still is) and required to run without subsidy despite tight regulation of fares and charges and of withdrawal of unprofitable services. There is currently little scope for new entry; although in India, entry is permitted into operation of containers services, entrants still have to hire locomotives and drivers from the incumbent so they are confined to planning and marketing the services and providing wagons and terminals. This change was in order to bring much needed investment into container terminals and rolling stock. In Russia some freight rolling stock was placed into the hands of a separate company that was privatized. Regulation in all three countries is essentially by a government department rather than an independent regulator, so a constraint on the growth of competition in the container market in India is that there is no independent body to whom the entrant may appeal if it believes it is being treated unfairly in terms of quality of service or even price. Although there has been some reform (for instance the transfer of Chinese Railways from the Ministry of Railways to a government owned company, China Railway Corporation) (Chen and Haynes, 2015) and more radical changes including vertical separation and introduction of competition have been proposed (Debroy Committee, 2015), reform to date in these countries has been limited.

The other interesting example of reform is Japan. Japan has always had a significant number of private railways offering regional and commuter services on a non-subsidized basis but earning a significant share of their revenue from property. However, until 1987, the main lines were all part of a national government owned vertically integrated company. In that year, the government railway was divided into 6 vertically integrated passenger companies, and 3 of these have subsequently been privatized through sale of shares (Ishida, 2011). There is still an element of fares regulation using benchmarking methods, though fares rarely change in Japan. In recent years, declining traffic for regional services due to population trends has led to some Japanese railways becoming unprofitable, thus leading to a form of "vertical separation" where the government takes financial responsibility for the infrastructure (though leases it back to the operator).

Conclusions

In the first century of its existence, the rail industry moved in many countries from a system of competing private railways to a state-owned monopoly. The principle exception to this was in North America, where private companies remained, whilst elsewhere some

rail systems had always been state owned. During this period, the railway was seen as having strong monopoly power, and was often heavily regulated, with strict controls on tariffs and a requirement to continue to operate unprofitable services and routes.

The growth of road transport as a competitor made this position unsustainable in most countries. In North America regulation was largely removed in 1980 under the Staggers Act on the basis that continued competition between privately-owned railways, with road haulage and with alternative sources of supply, made it unnecessary. US deregulation appears to have been very successful, leading to a big reduction in costs and freight rates. In Europe, earlier regulation by a separate regulator was generally removed as passenger services came to be mainly operated under public service obligations, whilst freight faced intensive competition from road. However, this left unregulated public monopolies about which there was much concern regarding efficiency. In 1991 the European Commission started a new policy of separating infrastructure from operations and introducing competition within the rail sector by opening entry to new train operating companies to compete with the incumbent either in the open market or on the basis of competitive tendering for public service contracts. This actually produced a new requirement for regulation, in that a system was needed to ensure non-discriminatory access and to check the efficiency of the monopoly infrastructure manager. Whilst the introduction of competition was generally seen as successful in improving services and reducing costs, there have been concerns that creating separate infrastructure managers and train operating companies means that there is no-one seeking to optimize the system as a whole, although track access charges and performance regimes may give some of the right incentives. There is evidence that vertical separation raises systems costs on more densely used railways because of increased challenge of dealing with co-ordination issues on busier networks.

Elsewhere, reform followed different patterns. For instance in South America, it became common to competitively tender long vertically integrated franchises for freight as well as passenger transport, whilst Australia adopted aspects of the European model. Japan split its national operator into vertically integrated companies and privatized the more profitable. Only a small number of countries, but including the very important rail systems of Russia, India and China, have so far stuck largely with the old model of tightly regulated government-owned monopolies.

Geography and the extent of demand are clearly relevant factors in this diversity of experience. For example, in Japan, population density in the major conurbations is such that passenger flows can be served by multiple, vertically-integrated routes. The dominance of a particular traffic type at high intensity, such as passenger traffic in Japan, supports the approach of having vertically-integrated passenger operations, whilst permitting access to freight services run by a separate company. Similarly, in the US the dominance of freight traffic supports vertically-integrated freight operations, with passenger traffic gaining access to these networks where required. Mixed networks such as those in Europe may warrant a different approach, where some form of vertical separation to support competition between operators on the same network, may be more appropriate, although careful consideration is needed of how to overcome problems of lack of coordination and misalignment of incentives in such a system.

It does therefore appear that there is no single model of rail reform that will clearly be preferable in all circumstances; a deep analysis of the circumstances of any individual country is needed to decide the best way forward.

The Increasing Importance of Cycling in Practice and Research

Since around the mid of the first decade of 21st century, cycling is booming in many cities and regions in the world, for example, cities such as New York, London, Paris, Santiago (Chile), and Muenster (Germany). Other cities, such as, Copenhagen and Amsterdam have a much longer cycling tradition. The increasing interest of policy makers and planners in cycling has resulted in a rapid increase in the number of academic papers in this area and several of these papers have high download and citation rates. As an illustration, of the ten most cited papers in the journal *Transport Reviews*, eight are about cycling.

Most papers are about the effects of cycling options like infrastructure provision or bike sharing systems on cycling levels. Despite this increased interest, the literature on the economics of cycling is limited. A possible explanation might be that several cycling policies are relatively cheap. Another reason could be that at first face there is no academic added value in discussing the economics of cycling, because all major cost and benefit categories are comparable to those of other transport projects (see next section). Another reason could be that decisions on cycling policies are generally made at the level of the local municipality and cities and towns do not often finance academic research, unlike national governments. A next reason could be that the variability in cycling over time can be relatively large, compared to traveling by car or train, due to season and weather effects. A final possible reason is that many cycling policies aim to improve comfort and safety, and these effects are more difficult to assess than travel time gains.

This chapter aims to discuss the economics of cycling and has one major conclusion: in estimating the economics of cycling one can easily, "do it wrong." The emphasis is on infrastructure policies, but several of the conclusions also apply to other cycling policies, such as promotion campaigns or fiscal policies. In addition, the focus is on western countries because those dominate in the academic literature in this area. The problems and pitfalls discussed, apply even more for developing countries.

As a point of departure, it is assumed that the welfare effects are calculated via a social cost-benefit analysis (SCBA). An SCBA is an overview of all (dominant) pros and cons of a project, in quantitative terms, and next in monetary values. Final results are expressed as indicators like "benefits minus costs" or the "benefit-cost ratio." SCBA is not further explained in this chapter.

Which are the Costs and Benefits of Cycling Policies?

Table 1 summarizes the dominant costs and benefits of cycling policies and the state of the art with respect to knowledge about the economics of each category of costs and benefits, as well as the main risks in their estimations.

The overall picture that emerges is that, at first face an estimation of the costs and benefits of cycling projects is about comparable to those of other transport infrastructure projects like road and public transport projects. The categories of costs and benefits are about the same, and the estimation of welfare effects can be based on the same methods as in the case of roads and public transport projects. But the state of knowledge on cycling projects really lags behind relative to those other projects. The quality of models is generally poor, there is very limited insight in the quantitative and even more so the monetary effects of effect categories, and as far as methods are available and applied there are substantial risks in estimating effects adequately, both quantitatively and in monetary terms. We later discuss some dominant risk categories.

Table 1 Current knowledge and main risks for dominant categories of costs and benefits

	<i>Current knowledge</i>	<i>Main risks</i>
<i>Costs</i>		
Value of land needed for cycling infrastructure, construction costs.	• Generally poor, at least in the academic literature. • Some knowledge for larger projects, especially if previously built examples are available, which applies to cities and countries with a cycling tradition. • If cities implemented comparable projects before: quite well known because of experience.	• Risk of underestimating costs - worldwide transport infrastructure projects often face substantial cost overruns.
Maintenance costs	• Maintenance costs are relatively limited.	• Uncertain, but small, so not very important.
<i>Benefits</i>		
Travel behavior related impacts—quality of models	• Models for cycling are quite poor.	• Relying on “bad models”—many effect estimates rely on (model based) forecasting.
Travel time of cyclists	• Only a few studies on values of time of cyclists.	
Comfort impacts	• Poor.	• Risk of completely overlooking these benefits.
Travel times of other road vehicles	• Values of time quite well known.	
Other accessibility effects (social exclusion effects, option values)	• Poorly understood, generally ignored.	• Risk of completely overlooking these benefits.
Wider economic impacts	• Poorly understood.	
Environmental impacts – emissions related	• Cycling emissions per km zero, emissions due to increased exercise (and food intake), and for producing bikes and infrastructure.	• Emissions for the construction of infrastructure generally ignored.
Other environmental impacts	• Poorly understood, certainly not quantitatively and in monetary terms.	• Exclusion or Pro Memory in evaluations and therefore not seriously considered.
Health impacts	• Often substantial. Rapidly increasing body of knowledge, and even tools for health impact assessment. • But still large uncertainties.	• Some risk of double counting as far as health is included in travel behavior decisions. • Interaction between cycling and other forms of physical activity. • Self-selection effects.
Safety impacts	• Poor data on incidents in many countries. • Often only aggregate risk factors.	• Incorrect use of aggregate risk factors. • Ignorance of the safety-in-numbers effect.

Pitfalls in the Evaluation of Cycling Policies

Costs

There is limited information, at least in the academic literature, on costs of cycling projects, and the quality of cost estimate. Roads and rail projects often face substantial cost overruns, so estimations for cycling projects could also be biased. But the importance of the costs of the common cycling infrastructure projects is relatively limited in absolute terms because cycling projects are generally relatively cheap. This also applies relative to the benefits (benefits of bike projects are often way higher than the costs) and relative to the volume of kilometers traveled. Therefore, despite the uncertainty, the importance of costs and cost estimates is not as large as in case of (major) roads and rail projects.

Maintenance costs of cycle infrastructure projects probably are relatively small, first because the construction of cycling infrastructure is relatively cheap, and secondly because wear and tear due to the use of infrastructure by bikes is very limited. Even on motorways the impact of cars on wear and tear is limited—it is the lorries with high axle loads (especially due to overloading) that cause almost all wear and tear of motorways.

Models

The estimation of the benefits, and next their welfare effects, to a large extent relies on forecasting changes in travel behavior. This applies to travel time related impacts, other accessibility related impacts, such as, health, safety, and environmental impacts. A major problem is that cycling is generally poorly included in transport models, even in countries with cycling tradition. The poor inclusion in models might first of all result from the fact that in most countries and cities world-wide cycling is way less common than driving or even than traveling by public transport. In addition for decades transport planning has adopted the predict-and-provide paradigm, at least for roads: forecast travel behavior, explore where infrastructure capacity is not sufficient, and provide new capacity. This paradigm resulted in a focus on (capacity) problems, more than on a focus on challenges, accessibility in general, and active modes.

Accessibility

Changes in travel times and the generation of new travel are important benefit categories of transport infrastructure projects in general. This also applies to several cycling infrastructure projects. The economics of estimates are relatively easy: travelers who face reductions of travel times generally evaluate those positively. Multiplying the number of trips that travelers make by travel time reductions per trip results in an estimation of the travel time saved, and next the multiplication of travel time saved by the marginal value of time results in the monetary value of those travel timesavings. The benefits of generated travel are generally estimated via the so-called rule of half: new travelers on average face travel time gains that are half of the full travel time gains of the infrastructure projects.

This methodology also applies to cyclists. But practice is not as simple as theory. Not only the absence of adequate models is a problem, there is also limited insight into the marginal value of time of cyclists. The studies that are available suggest that these values are generally quite high, higher than those for car and public transport users.

But cycling projects can also influence values of time of other road users, both positively (e.g., if more capacity for other vehicles becomes available because some drivers switch to the bike) and negatively (e.g., because road space is reallocated to bikes). Here the problem of poor models, and consequently poor estimates of (changes in) travel times and mode choice impacts of other road users are also relevant. The marginal values of time of other road users are generally quite well known. A risk may be that cycling projects mainly influence other road users on short urban trips, and the marginal value of time for short passenger trips generally is lower than for longer trips, so the risk is an overestimation of the value of these travel time changes for other road users.

But not all accessibility related effects of bike projects are related to the travel times of cyclists (and others). At least two other accessibility effects should be added, the first one being social exclusion, referring to the fact that some people have poor access to important destinations (work, shops, schools, medical services, etc.), often because they have no car available, because of a low income, and/or because of poor public transport services. Most studies on reducing levels of social exclusion via transport policies focus on public transport services, but the bike can be a relatively cheap, flexible, and healthy alternative. Estimating the welfare effects of lower levels of social exclusion is difficult. There are academics arguing that the willingness to pay of the people being socially excluded is not the right way to estimate those benefits. An alternative could be to estimate the value of lower levels of social exclusion by looking at policy measures (not) implemented to reduce these levels, and their costs and social exclusion effects. This results in the willingness to pay of politicians to reduce levels of social exclusion.

A next potentially relevant effect category could be option values: people might value the availability of options even if they do not use them. And they might be willing to pay for this availability — this at least was found in a few studies on public transport services: car users are willing to pay for having the option available even if they do not use these services.

Wider Economic Effects

Wider economic benefits are often-debated category of impacts of transport projects in general, and the uncertainty in the estimations is still large. For cycling projects, there is hardly any literature on these effects.

Environmental Effects

Emissions effects (e.g., CO₂, NO_x, PM) are generally estimated by multiplying travel behavior changes for each mode-by-mode specific emission factors. The poor quality of models also influences the estimation of emission effects, because travel behavior changes are difficult to forecast. Emission factors for other modes than the bike are generally available but should be selected carefully. For example, average emission factors for all car kilometers do not necessarily apply to those (urban) trips that are influenced by bike policies. Emissions due to cycling are zero, but cycling takes more energy than driving or traveling by public transport. If cycling would result in additional exercise and food intake emissions due to producing food are relevant, but there is only very limited knowledge in this area. Emissions of (changes in) travel behavior on noise and noise effects and their monetary valuation are quite well understood, so the main problem is the quality of transport models.

But cycling has more environmental effects: cities that prioritize active modes over cars are often considered to be more attractive. Terms like livability, the quality of the urban environment, and spatial quality are sometimes used to label these effects. The literature on these effects, including the monetary valuation of these effects, is very limited, although some studies have tried to estimate some of those effects via housing prices.

Health Effects

Health effects of cycling projects are often very substantial, and in some cases even the dominant benefit category. To some extent people might include health in their travel behavior decisions, so there is a risk of double counting if health benefits would be fully added to those related to travel behavior benefits and their valuations. But because according to some studies, the health benefits are often way larger than the travel behavior benefits, the size of double counted health benefits must be relatively small.

A large problem is probably that we poorly understand the interaction between cycling and other forms of physical activity. Do people who cycle more, substitute other forms of physical activity for cycling? Or do they exercise more, because they have a better condition, and, for example, take the stairs and not the elevator? In other words, cycling can replace, be added to, or even increase other forms of physical activity. But there is very limited knowledge on the interaction between cycling and other forms of physical activity.

Another problem for the estimation of health effects could be self-selection effects, it could be that specific categories of people more than average are inclined to cycle, for example, people who more than average think health is important, have a healthy

lifestyle in general, or who are fit because of genetic reasons. Health effects based on cross-section data of categories of people (cyclists and others) can therefore easily overestimate the health effects of (more) cycling.

Safety Effects

At first face estimating safety effects of travel behavior changes seems to be easy: estimate kilometers per mode, and multiply these with risk factors. But several problems emerge, the first one being the poor quality of models, and thus the estimation of travel behavior changes, as discussed earlier. Second, aggregate national risk factors are often not available for cycling because of the bad quality of registrations of bike incidents, and even bike levels. And if these are available, aggregate values do a poor job for specific travel behavior changes. For example the risks for car drivers on motorways are relatively low, but bikes do not or hardly compete with car trips for which motorways are used. Excluding motorways increases risk factors for cars. The third problem, from the perspective of adequate safety effect estimations, is that cycling becomes safer if cycling levels increase. This is referred to as the, *safety-in-numbers effect*. Explanations for this effect as mentioned in the literature include first that cyclists become more experienced, and that other road users become more used to cyclists. Second, road authorities provide better and safer infrastructure for cyclists the more people cycle. Note that safety effects might be partly included in people's value of time just as health effects, if, for example, people perceive cycling as relatively unsafe, they might be willing to pay more for shorter travel times, for example, due to a new cycle line.

Discussion

The overall picture that emerges is that at first face estimating the welfare effects of cycling seems straightforward and comparable to the estimation of the welfare effects of other transport infrastructure projects. Effect categories and methods are about the same. But practice is more problematic, due to the absence of adequate models, the lack of high quality data, very limited insights in several quantitative effects and their monetary valuation (like the impact of cycling on the urban environment), and difficulties in the estimation of some other effects, in particular health and safety effects.

In theory cities could learn from other cities that implemented cycling policies. But one has to be careful—context matters and this limits the transferability of results, at least across cities and countries with a different cycling tradition. To give a few examples, whereas in more egalitarian countries cycling is not linked to specific categories of people, it might be in other countries. And a hilly area could negatively influence utilitarian cycling, but positively some forms of recreational cycling. Also substitution of drivers or public transport users to cycling depends on the quality of alternatives and current use levels, and these factors have an impact of cross-elasticities.

How important is the general lack of knowledge for practice? First of all, not all topics discussed are equally important. The lack of adequate models, and the poor estimation of safety and health effects probably are most important. Second, in general the problem seems to be somewhat limited compared to road and rail projects. Cycling projects are often very cheap, and have high benefit-cost ratios. So, despite the uncertainty they are often no-regret. In several cases assessments might not be needed at all, cities can “just do it.” And cycling projects could be implemented via guidelines for road design or the design of urban environments, like in the Netherlands. Then an assessment for each project is not needed—the guidelines are used for planning, not stand-alone assessments of candidate projects. Of course these guidelines preferably should be underpinned using the current stage of academic knowledge.

A specific problem emerges with respect to safety; sometimes (expected) safety effects are barrier for the local municipalities to implement cycling policies. If for that reasons they would not implement these policies, which would have contra-productive effects, even for health. Some studies have compared the negative impacts of higher cycling levels on health because of incident risks, exercise, and the intake of pollutants. Those studies generally found that the positive impact of more exercise on health is way larger than the negative impact of incidents (and the intake of pollutants).

Biography

Bert van Wee is professor in Transport Policy at Delft University of Technology, the Netherlands, faculty Technology, Policy, and Management. In addition, he is scientific director of TRAIL research school. His main interests are in long-term developments in transport, in particular in the areas of accessibility, land-use transport interaction, (evaluation of) large infrastructure projects, the environment, safety, policy analyses, and ethics.

Introduction

The construction of high-speed rail (HSR) infrastructure is a significant component of the transport policy in many countries all over the world. From France and Germany to Japan and China. By HSR technology we mean the provision of rail services capable of speeds above 250 km/h on dedicated tracks (Albalade and Bel, 2017).

Governments of different political orientation are investing in HSR infrastructure, assigning significant amounts of public funds for its development with the declared aim of increasing the market share of railways. The demand for the new rail transport alternative comes from conventional trains, air, and road transport, and also from generated traffic, thanks to the combination of time savings, increased comfort and safety, and last but not least, subsidized prices.

The declared objectives for the implementation of HSR vary and goes from time savings, comfort and reliability to the reduction of global warming, and other negative externalities of competing modes of transport, regional development, and the like. In some countries the enthusiasm is more intense than in others. There is no a single pattern. The United Kingdom and the United States are now closer to building HSR infrastructure but until now they have been reluctant to give the definitive approval. Other countries, like France and Spain, have been keener on HSR than other European countries, like Norway or Sweden (de Rus, 2012). Spain is a peculiar case because with much less traffic density in the conventional rail network, it is the second country in the world measured in HSR kilometers, with the help of European Union (EU) funds.

Governments, the industrial lobbies, and the users, support this technological option for passenger travel. The price that users pay for HSR infrastructure and services in many routes is far from covering construction, maintenance, and infrastructure operation costs. This means that taxpayers contribute financially to the support of this transport option.

The question is not whether users, and other possible beneficiaries of HSR, would vote in favor of the construction of HSR lines. The question is whether they would be willing to pay (independently of what they actually pay) their social costs. The answer to this question varies widely depending on the local characteristics of the project: routes, urban zones crossed, bridges and tunnels required, volume of demand, per capita income, and the level of use of the capacity in competing modes.

The economic appraisal of a HSR project requires identifying the benefits and costs during its life, and calculates the social net present value. The cost-benefit analysis of HSR requires to compare the project with some “do something” alternatives. A realistic range of options has to be examined. The base case should be a “do minimum” and other likely investments should be examined as alternative “do something” options. These alternatives should be compared on an incremental basis to see whether the additional cost of moving to a more expensive option is justified. It is important to consider the main alternatives to be sure that the best alternative has been selected (de Rus, 2011).

A new HSR line in a medium distance interurban corridor changes the modal split, and this change will occur regardless of the social value of the HSR project. The final impact will heavily depend on the pricing policy of the government. The economic evaluation of HSR investment cannot be carried out without first determining which prices are going to be charged for HSR services. This is a key issue, as the market shares are very sensitive to pricing decisions taken in the public sector affecting the playing ground for intermodal competition. The public pricing decision regarding construction and maintenance costs of HSR infrastructure is crucial for the competitiveness of the railway operators, the intermodal equilibrium, and eventually the result of the appraisal of new lines.

There is considerable pressure on governments to build new HSR lines as if the investment were a kind of “now or never” decision. This does not seem to be the case with this technology. The construction of HSR infrastructure is irreversible and there is uncertainty associated with costs and demand. In these conditions the question of the right moment to invest is critical as the investment can be postponed in most cases. Hence, the optimal timing of the investment should be addressed in the case of a positive net present value. It could be profitable to build a line today and another in the future. Moreover, it is feasible to build a HSR rail track on parts of the overall line and use it for traditional trains at the same time as it is prepared for HSR services, which would operate once demand motivates building new tracks on missing links. There exist several “do something” alternatives (de Rus and Nash, 2007).

The Cost of a HSR Line

The cost of building and operating a HSR line consists of the construction and maintenance of the infrastructure, the acquisition, operation, and maintenance of the rolling stock and the external costs. The construction requires a specific design aimed at the elimination of all those technical restrictions that may limit the commercial speed below 250 km/h. These basically include roadway-level crossings, frequent stops or sharp curves unfitted for higher speeds so that, in some cases, new signaling mechanisms and more powerful electrification systems may be needed, as well as junctions and exclusive track ways in order not to share the right-of-way with freight or slower passenger trains, when there is joint use of the infrastructure.

Infrastructure costs include investments in construction and maintenance of the tracks including the sidings along the line, terminals, and stations at the ends of the line and along the line, respectively, energy supplying and line signaling systems, train controlling, and traffic management systems and equipment, etc. Infrastructure maintenance and operating costs include the costs of labor, energy, and other materials consumed by the maintenance and operation of the tracks, terminals, stations, energy supplying, and signaling systems, as well as traffic management and safety systems. Some of these costs are fixed, and depend on operations routinely performed in accordance with technical and safety standards. In other cases, as in the maintenance of tracks, the cost is affected by the traffic intensity. Similarly, the cost of maintaining electric traction installations depends on the number of trains running during operation.

Railway infrastructure also requires the construction of stations. Although sometimes it is considered that the costs of building rail stations, which are usually singular buildings with expensive architectonic design, are above the minimum required for technical operation, these costs are part of the system and the associated services provided affect the generalized cost of travel (e.g., quality of service in the stations reduces the disutility of waiting time). To these fixed costs we have to add the acquisition costs of the rolling stock and the operating and maintenance costs of running the trains.

There are other costs involved in a HSR project. For example, planning costs are associated with the technical and economic feasibility studies carried out before construction. These fixed costs, as well as those associated with the legal preparation of the land (expropriation or acquisition from current landowners), are not usually included in the published construction cost per km. There are other costs difficult to allocate to infrastructure or operation, as general administration, marketing, and internal training.

The operating costs of HSR services (train operations, maintenance of rolling stock and equipment, energy, and sales and administration) vary across rail operators depending on traffic volumes and the specific technology used by the trains. In the case of Europe, almost each country has developed its own technological specificities: each train has different technical characteristics in terms of length, composition, seats, weight, power, traction, tilting features, etc.

One of the reasons supporting the case for investing in HSR infrastructure is the alleged positive net environmental effect associated with the operation of HSR services once the intermodal substitution effects are included. HSR trains attract passengers from road and air with higher environmental externalities and, when the deviation of traffic is substantial, as it potentially the case in medium-distance corridors, the net effect on the environment of investing in HSR might be positive.

The environmental externalities of HSR point in two directions. One is positive, due to its substitution effect on air and road traffic, although it requires a significant deviation of passengers from these modes as well as high load factors in the HSR to offset the pollution associated with the production of electric power consumed by high speed trains. The other is negative: HSR lines need land, crossing areas of environmental value. The rail track creates a barrier effect in the affected territory, produces noise, and generates visual intrusion on the landscape.

The net environmental impact will depend on the reduction of environmental externalities in other modes of transport that lose traffic in favor of the new mode. Moreover, the emission of greenhouse gases during the construction period is substantial and it may take decades of HSR operation to compensate for the emissions caused by construction. The net effect depends on the value of the affected areas, the number of people affected, the benefits from diverted traffic, and so on. The net impact is very difficult to assess, without contemplating the circumstances in a particular corridor, and a key element is the volume of demand attended by the HSR.

The Benefits of HSR

Leaving aside income transfers, HSR generates different social benefits, basically timesavings, higher reliability, comfort and safety, and the reduction of congestion and accidents from alternative modes. When users shift to HSR from buses, cars, or airlines, some avoidable costs add to total benefits. Other benefits could be added to the list though they are more controversial, as the spatial effects (tunnel effect of HSR in contrast with the corridor effect of conventional rail) or the agglomeration benefits.

The direct benefits of HSR investment come from existing passenger-trips using conventional railway services in the corridor, the deviated demand from other transport modes and the induced passenger-trips after the reduction of the generalized cost of travel. The door-to-door user time invested in a trip includes access and egress time, waiting time, and in-vehicle time. The total user timesavings will depend on the conditions in the initial transport mode.

The case of road transport is quite different with access-egress and waiting time, playing a decisive role in the generalized costs and eventually in modal choice. In the case of a HSR line of a 500–600 km length, car passengers shifting to HSR benefit from travel time savings but they lose with respect to access, egress, and waiting time. Benefits are higher than costs when travel distance is long enough, as HSR runs, on average, more than twice as fast as the average car. As the travel distance gets shorter the advantage of the HSR diminishes as in-vehicle time loses weight with respect to access, egress, and waiting time. Nevertheless, in choosing between car

Figure 1 Market shares of rail, road, and air in France. Source: UIC, 2018.

and HSR, a key factor could be whether the traveler will need a car at his destination. This, in turn, could depend on trip purpose and the availability of mass transit at the destination. Similarly, the number of people traveling together could matter as the marginal cost of a second person traveling in a car that is already making the trip is near zero. Moreover, it is usually assumed that trip quality is higher for HSR than for auto travel. In some ways, that may be true, but not in all ways. For example, one can stop when and where one likes and it is easier to carry luggage with oneself if traveling by car.

In the case of air transport (Figs. 1 and 2), the situation is also different. In-vehicle time is longer by train but it is assumed that the user saves access, egress, and waiting time, and enjoys additional service quality. The evidence is that the money value of time of access-egress and waiting time are of the order of 2 and 1.5 times higher, respectively, than in-vehicle time and hence, even in the case of longer door-to-door travel time after the shift, the value of time savings of a passenger shifting from air to rail could be positive, as far as the values of time of access-egress and waiting time are high enough to compensate the losses in-vehicle time.

Figure 2 Rail market share on the rail + air market in France (passengers). Source: UIC, 2018.

Benefits also come from induced demand. The new passenger-trips of HSR may come from different sources: completely new generated trips; trip redistribution, i.e., trips that were made to a different destination without the project; diverted demand from other modes of transport; and finally, route or time reassignment. In the three first cases the number of passenger-trips increases for the project and so we have to account for the willingness to pay of both the deviated and the generated demand.

Promoters of HSR projects tend to emphasize the indirect effects, wider economic impacts, and regional development instead of the direct effects. It is true that transport investments produce other alleged benefits beyond the direct benefits already discussed, but it is unclear whether these additional benefits are new ones or double counting. Moreover, some genuine indirect benefits exist but in many cases they could be associated with any other infrastructure project in general, and not exclusively with high speed, so even if the benefits increase the social return on the investment in transport, they do not necessarily place HSR in a better position over other relevant alternatives (Vickerman, 2009; Preston, 2017).

Should we worry about the wider economic benefits in the case of HSR investment? Additional benefits are not expected to be very important in the case of HSR infrastructure. The reason is that freight transport does not benefit from high speed and therefore the location of the industry is not going to be affected by this type of technology. Moreover, in the case of the service industry, HSR may lead to the concentration of economic activity in the core urban centers.

Recent research suggests that agglomeration benefits in sectors such as financial services may be greater than in manufacturing. This is relevant to the urban commuting case but arguably it is also important for some HSR services (e.g., the North European network which links a set of major financial centers and may be used for a form of weekly commuting). It may be erroneous to conclude that scale economies and agglomeration economies (productivity impacts) are only found in manufacturing and freight transport.

Intermodal effects could be one of the main benefits of HSR. The critical issue is whether price is higher or lower than marginal social cost in the alternative mode of transport. When price is below marginal cost in the original transport mode, society benefits from the diversion of demand to the new transport mode (assuming price is at least equal to marginal cost in the new mode). This could happen because of the reduction of excessive congestion, or pollution. In the case of a positive externality the opposite might occur, and the indirect effect could be negative when the price is above the social marginal cost in the original transport mode, for example, if the reduction of demand in the original transport mode forces the operators to reduce the level of service (e.g., frequency), thereby increasing the generalized cost of travel.

The key point is whether the original transport mode was optimally priced. Although it has been argued that the reduction of road and airport congestion is a positive effect of HSR, this is only the case with suboptimal pricing. When road and airport congestion charges internalize the external marginal costs, there are no indirect benefits from the change in modal split. This can be viewed from another perspective. The justification of HSR investment based on indirect intermodal effects should be first compared with a “do something” approach, consisting of the introduction of optimal pricing.

Intercity bus services operate under concession contracts in many countries and so although they keep the regulated timetables unchanged in the short run, the financial difficulties will emerge later, leading to contract renegotiations. Eventually, users and/or taxpayers (or workers) will have to pay for the adjustment in the medium-term.

Airlines operate in open competition and the external shock in demand originated by the introduction of HSR services in medium distance corridors jeopardizes the financial equilibrium of the companies. The unavoidable response is to diminish frequencies when the loss of traffic is substantial. The drop in the number of flights per hour increases total travel time when passengers arrive randomly (shuttle services), or decreases utility when they choose their flight in advance within a less convenient timetable.

Regarding the spatial effects, HSR lines tend to favor central locations, so that if the aim is to regenerate the central cities, HSR investment could be beneficial. However, if the depressed areas are on the periphery, the effect can be negative. The HSR could also allow the expansion of markets and the exploitation of economies of scale, reducing the impact of imperfect competition and encouraging the location of jobs in major urban centers where there are external benefits of agglomeration. Any of these effects are most likely to be present in the case of service industries. Location effects are dependent on many factors and it is difficult to determine a priori whether the center or the periphery will benefit from the relocation of the economic activity.

There is evidence on the increase in land values or on the increase in the GDP of places where HSR stations are located. However, the problem is to disentangle genuine additional benefits from mere relocation of economic activity from other areas of the country, or from a simple reflection of the already-measured timesavings into property values.

A Final Assessment

HSR infrastructure is expensive, irreversible, and requires a high volume of traffic to be socially profitable. In spite of all the advantages of HSR investment over competing modes, there are only two lines in the world commercially viable, the Paris-Sud Est and the Tokaido. Therefore, careful consideration should be given to the introduction of HSR in new corridors given the significant amount of public funds involved.

The investment in HSR infrastructure is one of the feasible “do something” alternatives to deal with transport-capacity problems in passenger intercity corridors. It is not the only one but the economic case for this option is more likely when there are capacity constraints in the conventional rail network, roads, and airports; and the release of capacity generates additional benefits for freight, long-haul flights, and other side effects of the marginal capacity that avoid major investments. Another potential benefit of HSR

investment is the reduction of environmental externalities, though this depends on the volume of demand deviated from less environmentally friendly transport modes and whether the demand is high enough to compensate the negative externalities during construction, and also other neglected but significant impacts as the barrier effect, noise, and visual intrusion.

There are two approaches for the ex-post economic appraisal of the HSR. One is the traditional cost-benefit analysis using real data. Another is to apply statistical methods for causal inference with observed data with and without the project to estimate the economic impact of the introduction of the HSR.

The direct benefits of HSR in terms of timesavings, willingness to pay of generated traffic and avoidable costs in competing modes, are usually not enough to compensate for the fixed construction costs and the operating costs. The magnitude of direct benefits depends on the prevailing conditions without the project. The benefits also depend upon whether there is an upgraded conventional railway able to run above 150 km and convenient air services. When this is the case, it is difficult to find a socially profitable investment based exclusively on timesavings, generated traffic and cost savings in the conventional modes unless the demand is above 10 million passenger-trips. The upper bound could be much higher, particularly when the deviated traffic comes mainly from air transport in a context where this mode of transport is delivering good and competitive services (de Rus and Nombela, 2007).

Graham and Melo (2011) have estimated the potential agglomeration benefits for the HSR in the United Kingdom based on the gravity models, to deduce changes in flows resulting from travel timesavings. They estimated an upper bound of 0.19% and a lower bound of 0.02% of UK's GDP. They conclude that "even in the best-case scenario for improvement in long-distance travel times and market share of classic and high-speed rail, the potential order of magnitude of the agglomeration benefits is expected to be small."

They also estimated the spatial economic impact of the introduction of HSR Madrid-Barcelona using a difference-in-differences specification with province and year fixed effects. Although they found positive average treatment effects for provinces with stops on the HSR line (4% for economic output, 3.3% for numbers of firms, and 1.1% for labor productivity), they did not find significant effects on employment, and though they found evidence of increased economic activity in provinces with HSR stations, measured by numbers of firms, they were not able to distinguish whether these gains were relocation or growth. In a more recent (still in progress) research for the Madrid-Barcelona line they conclude (provisionally), "The results indicate that predictions of a positive impact on the economic performance of regions receiving HSR have not taken place, at least in the short to medium term. In the case of the Madrid-Barcelona HSR corridor, our results show that there are no significant differences in the pattern of regional economic growth before and after the HSR corridor between the treated and untreated provinces" (Carbo et al., 2018).

Finally, the economic evaluation of long-lived infrastructure requires a careful construction of the counterfactual and there are many assumptions that might seriously bias the results. This is the case of transport pricing during the lifespan of the project. Pricing policy needs to be explicitly treated. We need to consider how the alternative transport modes are going to be charged. For example, the government could charge air and road transport below social marginal cost and then justify a massive rail investment as a second-best policy to change the modal split, or it could optimally price all transport modes and then evaluate the optimal way to expand capacity. The final result might be quite different.

Socially profitable or not, once the HSR infrastructure is built the costs are sunk, and this irreversibility affects to more than half of the total costs (lower density lines presents a higher proportion). Once the line is built, the marginal cost of additional traffic is quite low compared with the ex-ante marginal cost. Prices well below average total costs are common in many HSR lines around the world, fostering demand and the expansion of a network in regions or countries where there were superior alternatives to solve the transport problem at stake.

Summarizing, HSR is a mass transport technology to attend medium distance intercity mobility. It requires a quite high volume of demand to compensate the high sunk costs of the construction of its infrastructure. The majority of HSR lines in the world are far from breaking even and therefore they are sustained both with commercial revenues and public funds. Under these circumstances, the development of a HSR network is not determined by market forces and therefore the economic appraisal of projects is indispensable to determine its social profitability.

Introduction

Railways have an important role in the economic development in many countries, which can explain why changes within this industry have early been one of the core subjects of economic analysis. Specifically, the railway sector has undergone organizational transformations since its early stages, where questions regarding ownership and regulations of production or pricing of goods and services have been at the center of attention. One reason for the regulations is that the railway system (especially the infrastructure) is considered to have the characteristics of a natural monopoly—that is, an industry in which the market equilibrium results in one firm producing the output. Economies of scale, scope, and density can be reasons for a natural monopoly. Other market failures, especially externalities, have also played a role in recent transport sector regulations. It should, however, be acknowledged that regulations may be the result of interest groups' influence, and not only a means for ascertaining efficient service delivery.

A rail cost function has been (and still is) an important tool in analyzing the industry's supply side, both from an economic and an engineering perspective. Specifically, a rail cost function can be used to analyze the effect of changes related to the railway system and support decision-making. One example concerns the understanding of the impact of different forms or structural alternatives for providing rail transport, such as the effects of (de)regulation, the extent of economies of scale, scope, or density, or analyzing the cost impact of innovations and investments. Results based on a proper rail cost function can thus serve as input in forming new policies, in appraisal of transport investment, renewal and maintenance, or as means for analyzing the productivity and cost efficiency of rail transport.

Uses of Cost Analysis in the Railway Sector

A rail cost function is a way to characterize the provision of rail transport. In particular, it can provide information on the existence and level of economies of scale, density, or scope, which is essential for obtaining a better or even optimal allocation of resources. Economies of density in railways are present if adding more traffic on a fixed network leads to a lower average cost, while there are economies of scale if lower average costs are generated by an increase in both network size and traffic. There can be economies of scope if different types of traffic on a railway imply lower average costs compared to running each traffic type on separate railways. Scope economies within a train operating company may also emanate from operating both passenger and freight train traffic under a common organizational framework. Information on the economics of scale, density, and scope is for example relevant for the choice between an integrated railway system vis-à-vis a vertical separation between infrastructure management and train operations, or a horizontal separation between passenger and freight train operations. For example, do economies of scope disappear from a vertical and/or horizontal separation and are economies of density lost when train operators compete on the same line, and does increased competition outweigh any negative effects? It is also relevant regarding the optimal network size that the infrastructure management's separate regions or units are responsible for.

Whether the railway services are produced in-house or contracted out may also have an impact on costs. This is referred to as competition for the market through a bidding process where the winner of a contest will deliver train services or maintenance and renewal of rolling stock or of infrastructure. Yet, another form of competition has been introduced for train operations, with an "open access" to the tracks where operators compete with each other on the same train lines in the annual timetable. Although the use of competition has increased, the railway industry is generally not a perfectly competitive market and so market forces will not necessarily drive down costs to their minimum. This has motivated cost efficiency analyses in railways, which can be useful in benchmarking studies and as input for policies that aim to reduce efficiency gaps.

Europe's vertical separation between train operations and infrastructure management that started in the 1990s has generated a need to specify rail (infrastructure) cost functions and derive marginal costs. In particular, the use of track access charges is a requirement within the European Union. According to the (short-run) marginal cost pricing principle, a track access charge that is based on the marginal cost will create an efficient use of the infrastructure. Examples of the negative externalities (third party costs) created by the train services are wear and tear of the infrastructure, noise, accidents, and congestion-related delays. In determining the wear and tear costs, both for the trains and from trains on the infrastructure, engineering methods on deterioration mechanisms together with rail cost functions have been applied. The use of rail cost functions is thus a multidisciplinary field, with advantages of combining economic and engineering approaches.

There are indeed many cases where a rail cost function can be useful. The proper specification of the function depends on the question one wishes to investigate or answer. Next, we provide a short introduction to cost functions and the modeling approaches used for railways. This is followed by a brief overview of different types of rail cost functions and their functional forms within the empirical research. Lastly, it is presented how aspects of rail transport operations and infrastructure provision can be captured in the cost function.

Cost Functions

As is the case in many other industries, modeling of the railway system involves the use of multiple inputs to produce multiple outputs and their combinations are limited by the production possibilities set of the firm(s). The properties of the production technologies can be analyzed using a production function that relates the maximum output(s) that can be obtained by the input(s). However, this requires a proper representation of the technology and data on the input quantities used. A cost function specifies the relationship between output level(s) and input price(s), and is one way to incorporate multiple outputs with unknown input quantities, with the assumption that firms try to minimize costs and that this determines the mix of inputs used in the production. Hence, the cost function only requires information on the input prices rather than measures of the inputs that are necessary for specifying a production function.

Specifically, the use of a (rail) cost function is based on the duality between production and cost functions, which means that the cost function is derived from the production function using the assumption that the firm chooses a combination of inputs that minimizes cost given input factor prices. Hence, assumptions required for duality and a well-behaved cost function are that the (railway) firm is cost minimizing and that the input prices and the outputs are exogenously determined, which is the case on a competitive market. However, it can be contested that railway firms operate on such markets, considering the public provision, subsidies, and/or regulations within the railway industry. Still, input prices are to a large extent exogenously determined, as rail undertakings often need to purchase the inputs in competitive markets. Moreover, infrastructure provision has little choice but to accommodate more or less traffic, while (passenger) train operators often have to supply a minimum train service level set by the regulator.

In addition, there is a set of properties of a well-behaved cost function that follows from cost-minimization; it should be nonnegative, nondecreasing in input prices, positively linearly homogenous in input prices, and concave in input prices (see [McFadden \(1978\)](#) for more details). Whether these conditions are met or not depends on the specification of the cost function and its functional form, where one can impose restrictions such as symmetry and homogeneity of degree one in input prices, while some specifications require checks on the concavity condition after estimation. However, before a rail cost function is specified, a modeling approach needs to be considered, which depends on the questions one wishes to investigate or answer, as well as what type of data is available.

Modeling Approaches for Railway Costs

The main approaches used in analyzing railway costs can be divided into the following:

- a top-down approach using empirical models; and
- a bottom-up approach using mechanistic models.

The models need not be in the either of these extremes; there are also hybrids or combinations of the bottom-up and top-down approaches (see, for example, [Smith et al., 2017](#)). Moreover, the modeling approaches can be either deterministic or stochastic, where the former makes predictions that exclude random variation, while the latter predict distributions of potential outcomes.

The top-down approach tries to establish relationships with factors that may explain variations in costs, while the bottom-up approach considers the mechanisms behind these relationships on a more disaggregate level. The top-down approach is often applied to analyze economies of scale, scope, or density, or the impact of organizational changes such as (de)regulation. It is also a common approach when establishing relationships between output and (aggregate or disaggregate) costs, such as the impact traffic has on costs for providing rail infrastructure.

The bottom-up (engineering) approach can also be used in establishing cost relationships but starts at a lower level to model the physical mechanisms behind these relationships. This approach has been used to estimate the relative cost impact of different vehicle types or specific characteristics of a vehicle. In short, simulations are performed based on a set of engineering models to

provide estimates of the damage on the infrastructure caused by a certain characteristic of a vehicle or train operation. Another application concerns damages done to the vehicle using an infrastructure with a set of characteristics. These damages are then linked to maintenance activities or costs that can be implemented in order to reduce the need for future maintenance. In doing this, a rail cost function is useful (and required).

Both the top-down and bottom-up approaches have its merits and disadvantages. The strength of the former is its simplicity and practical value by using actual costs to establish casual relationships between a variable and changes in the cost (while controlling for confounders). It struggles, however, in identifying causal relationships when the underlying mechanisms are complex and possibly highly correlated. Its causal explanations and predictive power can be questioned if there are underlying mechanisms or mediating variables that, when altered, could impact the established relationship. The bottom-up approach, on the other hand, explicitly models the underlying mechanisms. However, lack of data limits the use of this approach, which can imply that some mechanisms are not well understood, but also, even if they are understood, more mechanisms require more parameters that can add uncertainty to the model. For example, rail infrastructure cost data is usually more aggregated than the predictions made with a bottom-up approach: A mechanistic model can generate measures of various damage mechanisms caused by traffic; yet, to form a cost estimate, two further stages are needed. The first is to work out the appropriate remedial interventions needed to rectify the damage and the second is to cost those actions. The later stage is particularly problematic and usually uses simple unit costs that ignore such factors as economies of scale. The modeling approaches can thus complement each other in rail cost analyses, using their best features.

Specification of a Rail Cost Function

One of the first functional forms in analyzing railway costs were linear cost functions, where costs (C) were determined by a fixed component (α) and a component proportional to output (βq), that is, $C = \alpha + \beta q$. Apart from lacking the important input price (p) variable(s), a major criticism against this function is that it implies constant marginal costs and therefore assumes that there are no diminishing returns. This is not the case for the Cobb–Douglas cost function, which is dual to its production counterpart, and can be expressed as:

$$C = e^{\alpha} \left(\prod_{k=1}^m q_k^{\beta_k} \right) \left(\prod_{r=1}^n p_r^{\gamma_r} \right) \quad (1)$$

which in logarithmic form is:

$$\ln C = \alpha + \sum_{k=1}^m \beta_k \ln q_k + \sum_{r=1}^n \gamma_r \ln p_r \quad (2)$$

and can be estimated using standard linear techniques, for example, ordinary least squares, where α , β_k , and γ_r are the parameters to be estimated. Yet, this cost function assumes that the cost elasticities are constant. In other words, it assumes constant returns to scale and density as the elasticities with respect to output are constant, and a unitary elasticity of substitution between input factors (i.e., a proportional change in the input price ratio will lead to an equiproportional change in the input factor ratio). A more flexible functional form is the translog specification (Christensen et al., 1973; Christensen and Greene, 1976), which can be expressed as:

$$\ln C = \alpha + \sum_{k=1}^m \beta_k \ln q_k + \sum_{r=1}^n \gamma_r \ln p_r + \frac{1}{2} \sum_{k=1}^m \sum_{l=1}^m \beta_{kl} \ln q_k \ln q_l + \frac{1}{2} \sum_{r=1}^n \sum_{s=1}^n \gamma_{rs} \ln p_r \ln p_s + \sum_{k=1}^m \sum_{r=1}^n \delta_{kr} \ln q_k \ln p_r \quad (3)$$

This is a second-order approximation of any cost function, which relaxes the assumptions of constant returns to scale and density, as well as the unitary elasticity of substitution between inputs. Note that linear homogeneity of inputs prices can be imposed by using one of the input prices as the denominator when dividing the cost and the other input prices.

As mentioned previously, the well-behaved cost function presumes that firms or decision-making units are cost minimizing. However, they are not always successful in this objective, and models have been developed to consider cost inefficiency. In general, a component (u) for the difference between actual costs (C) and minimum costs ($C^{\min}$) is introduced in the model specification. Using the logarithmic form, the actual cost is then expressed as:

$$\ln C = \ln C^{\min} + u. \quad (4)$$

The level of cost efficiency is $C/C^{\min}$, which from Eq. (4) is e^{-u} . Modeling cost efficiency can be useful in benchmarking studies of railways, with an aim to identify the decision-making unit (i) that lies on the cost (minimizing) frontier and the level of inefficiency that the other units have.

Observations over time (t) are common and useful in (rail) cost analyses. This allows a cost specification that reflects technical change, which means that the cost frontier changes over time. One can include a (linear or quadratic) trend variable in the cost function or the less restrictive time dummy variables. Furthermore, the time dimension makes it possible to consider the dynamics in rail costs. For example, maintenance costs in one year can have an impact on the maintenance carried out in the subsequent year(s); a (sudden) change in traffic can result in a change in maintenance activities, which implies a temporary deviation from the original cost-minimizing plan that may take time to adjust back to (e.g., due to budget and/or planning

restrictions). Using the Cobb–Douglas cost function in logarithmic form, a dynamic cost model for firm i in time t can be expressed as:

$$\ln C_{it} = \alpha + \theta \ln C_{it-1} + \sum_{k=1}^m \beta_k \ln q_{kit} + \sum_{r=1}^n \gamma_r \ln p_{rit} \quad (5)$$

This is a special form of the autoregressive distributed lag model, which also includes lagged explanatory variables. In addition to the effect of for example output ($\ln q_k$) on current costs, captured by β_k , the model captures how this effect traces into subsequent year(s) through the term for lagged costs, θ . Specifically, when there is no tendency to change costs, the “equilibrium cost” is $\ln C_{it} = \ln C_{it-1} = \ln C_i^e$, and, from Eq. (5), it can then be expressed as:

$$\ln C_i^e = \frac{\alpha}{1-\theta} + \sum_{k=1}^m \frac{\beta_k}{1-\theta} \ln q_{ki} + \sum_{r=1}^n \frac{\gamma_r}{1-\theta} \ln p_{ri}. \quad (6)$$

where the effect of a change in an output ($\ln q_k$) in the current period and subsequent period(s) is $\frac{\beta_k}{1-\theta}$.

To choose between different modeling approaches and rail cost functions, the starting point is to specify the objective of the analysis. This establishes the level of detail required; is it necessary to model underlying mechanisms or are direct relationships between variables enough? Is the whole railway system considered, or parts (and subparts) of the system such as infrastructure provision (total costs or costs divided between track superstructure, track substructure, signaling equipment, etc.) and train operations (costs for freight transport or passenger transport)? This will impact the decision on which outputs and inputs to use in the specification.

Common metrics for the output of the system are train-, vehicle-, and seat-kilometers (outputs that are delivered as part of the rail system) and ton- and passenger-kilometers (outputs that have been consumed, the so-called final outputs). Both types of outputs can be important to include in the cost function. For example, to assess the efficiency of infrastructure provision, it is important to consider that a line with a high train frequency is costly to maintain (e.g., due to short and fragmented time slots available for maintenance) and that higher axle loads imply more wear and tear of the tracks. Also, for train operation efficiency, both the frequency of service (train-kilometers per route-kilometers) and seat-kilometers can be useful representations since both provide information about different types of quality aspects. A high number of seat-kilometers does not necessarily imply high frequency (it is possible to use longer trains to increase seat-kilometers) and vice versa.

It can also be relevant to consider the heterogeneity in costs between different types of passenger train services such as high-speed, interregional, regional, or suburban trains, as well as for freight train services where different commodities may imply different costs per ton-kilometer. The next section is devoted to transport operations costs and how to deal with the heterogeneity in outputs. This is followed by a section on infrastructure provision costs, which must also address a problem related to the heterogeneity of outputs: information on axle load, running gear, and the speed of the vehicles running on the network can be important for explaining variations in the wear and tear costs.

As input prices vary, the rail cost function should include these for ascertaining that the duality between the production and cost function prevails. Excluding input prices that are not constant across the observations implies a mis-specified model; there are, however, econometric techniques that can control for general (cross-section wide) input price changes. Examples of input price information that are useful are price of capital (rolling stock and/or materials for other assets used in the production), labor, and energy.

Transport Operations Costs

Transport operations refer to the part of the transport production process where vehicles are run on a network and the output may be regarded as the transport of passengers or freight. Passenger-kilometers and freight ton-kilometers are therefore a common basis for rail output measurement. Researchers and rail managers have often added these together to form a measure of output known as traffic units, although this will only be appropriate if they cost similar amounts to produce. Otherwise, increasing productivity may simply appear because the railway is moving toward producing more freight traffic and less passenger traffic, or vice versa.

Strictly, a rail transport service can be described in terms of the provision of transport from an origin to a destination at a specific point in time and of a specific quality. A rail passenger operator that runs trains between numerous stations several times per day has therefore a vast number of products on offer. However, as well as being infeasible to characterize in a cost function, this issue is only distorting if the products have significantly different cost characteristics, and traffic on them is increasing or decreasing at different rates.

Furthermore, in passenger transport, the speed of service and the stopping pattern of trains have an impact on costs. This could be measured directly, for example, average speed of trains and number of stops, or, alternatively, by splitting traffic into different categories, for example, commuting and long distance. In any event, frequency of service is an important quality attribute and railways operate trains at different frequencies to accommodate different patterns of demand. There is therefore a clear benefit in distinguishing between train-kilometers, vehicle-kilometers, and ton-kilometers. The advantage of a cost function is that multiple output measures can be incorporated within the cost function.

Freight traffic also has a multiplicity of outputs, where the transport cost for a ton of freight may vary depending on whether it is a dense product or not, and the form it is in, considering their impact on the gross weight of the wagon and on costs for loading and

unloading. This suggests that loaded-wagon-kilometers may be a better output measure than ton-kilometers. Moreover, the output measure may need to distinguish between for example bulk traffic and intermodal container traffic. If overall ton-kilometers are used, the estimated cost relationship would be distorted if there is a shift from transporting bulk aggregates to lighter containers, as has been the case in many railways.

There are indeed several challenges in specifying outputs in cost functions for transport operations arising from the multiplicity of outputs. From an econometric point of view there are two ways to view this problem. Firstly, multiple outputs are simply an issue of scope, that is, the firm produces multiple products. Thus, the issue is how disaggregate the output measure should be, trading off accuracy in specifying the production process with data and estimation accuracy constraints (similar to the issues with input prices). Alternatively, multiple outputs can be characterized by continuous attributes. So, train-kilometers could be used as the primary output, but then several characteristic variables, such as the length of trains, average speed of trains, and service type indicators, could be used. Therefore, the problem is not seen as scope, but variations in the quality or other characteristics of relatively generic high-level outputs. Both approaches, and indeed a mixture of these two approaches, are used by practitioners. Indeed, some researchers have included many output measures and characteristics of output in their cost functions using a device known as a Hedonic function, which was first used by [Spady and Friedlaender \(1978\)](#). This function has the advantage of avoiding consuming too many degrees of freedom in the estimation process, leading to greater precision in the estimated relationships.

Input price data is often difficult to come by. This is for two reasons. Firstly, available accounts from train operators may not produce a detailed breakdown in cost. The implication is that, in addition to costs for, for example, staff and rolling stock, there is often a large proportion of total cost which is allocated to “other”: a category by definition to which it is impossible to assign an input and thus construct a price. Secondly, and more fundamentally, the complexity of the production process, associated heterogeneity of inputs, and resulting problem of joint costs, means that there is a limitation to the extent that enough input prices can be constructed such that the diversity in inputs can appropriately be characterized in the cost function.

Infrastructure Provision Costs

Building and managing railway infrastructure involves using a large amount of resources that, after implementation, cannot be redeployed; costs are sunk. After an investment in infrastructure, the assets need to be maintained and eventually renewed due to wear and tear. A cost minimizing plan would imply that the infrastructure manager carries out maintenance—a cost that is increasing over time due to accumulated use—until it is cheaper to renew the infrastructure (based on, e.g., annual equivalent cost comparisons). This type of life-cycle asset management requires information on the wear and tear costs (as well as other types of costs) caused by traffic, which is also necessary for determining marginal costs of infrastructure use. Indeed, rail cost functions can be used to predict how variations in traffic affect life-cycle costs and thus the cost-minimizing plan for the asset, and also to determine the (short-run) marginal cost per train- or gross ton-kilometer. Evidence suggests that the wear and tear cost elasticities with respect to traffic is around 0.25–0.45 for maintenance, and around 0.5 for renewals ([Nash, 2018](#)), indicating that the average costs for these activities decrease with traffic.

Gross ton-kilometer is a common output measure in analyses of rail infrastructure costs as it is an important driver of the wear and tear of the infrastructure. Still, variations in the characteristics of the vehicles such as axle load, bogie type, and speed can cause different levels of damages. There is a growing interest in differentiating between vehicle characteristics and their impact on infrastructure costs, where the use of a bottom-up (mechanistic) approach is common. However, as described previously, a combination between a bottom-up and top-down (empirical) approach can be particularly useful in this case; the former is good at predicting the relative damage caused by vehicles, while the strength of the latter is to establish a relationship between these damages and actual costs using few restrictions on the elasticities of production.

To establish a relationship between traffic and costs, it is important to properly characterize the nature of the rail infrastructure. This can be done by including measures of infrastructure characteristics such as track length, switches, bridges and tunnels, as well as measures of the capability and condition of the infrastructure such as maximum line speed, maximum axle load allowed, and rail age. In general, measures that can explain variations in infrastructure costs and in traffic are important to include in the rail cost function in order to capture the short-run marginal costs of traffic. In addition, such measures are also essential in an efficiency analysis of infrastructure provision.

When analyzing infrastructure provision costs, one needs to be aware of that the data generation processes are different between maintenance and renewal costs. As described earlier, maintenance activities are carried out over the life-cycle of the asset, while a renewal is undertaken to restore the asset to its original condition. The causal structure between traffic and maintenance cost is based on the additional wear and tear caused by extra traffic, requiring an increase in maintenance activities within the same year and possibly also in subsequent year(s) to keep a certain level of performance and reliability of the infrastructure (minimize costs of the asset's life-cycle). The rail maintenance cost function is thus usually specified as traffic (and other variables) in one year explaining maintenance costs in the same year. It can also include a dynamic component (lagged maintenance costs) to analyze whether intertemporal effects are prevalent [Eqs. (5) and (6)].

The renewal marks the “death and rebirth” of the asset, which means that the time intervals between these activities on a railway line are relatively long, typically longer than 20 years. Hence, to establish a relationship between traffic (and other factors) and the lumpy renewal cost, relatively longer time series need to be used than what is required for establishing the relationship for maintenance costs.

In specifying a renewal cost function, it is important to consider that a *temporary* increase in traffic implies that future renewals will be carried out earlier than originally planned. A permanent change in traffic may also result in a change in the length of the renewal intervals. Both consequences affect the present value of renewal costs (and can also have an impact on the size of the renewal cost). One approach that has been used to capture these intertemporal aspects is survival analysis, where it is estimated how different covariates affect the risk of renewal (Andersson et al., 2016). Another approach is to specify the renewal cost function as a two-part model, where the probability of a renewal is estimated in the first part and the size of the renewal is estimated in the second part (Andersson et al., 2012).

Introduction

International merchandise trade implies moving cargo across borders, whereas international trade in services either requires people to travel or to get access to cross border communications. Hence, transportation derives from the volume traded and the distance between the traders. Currently, maritime transport carries more than 80% of international merchandise trade. Airlines, railways, or trucks transport the remaining cargoes in international trade (UNCTAD, 2018).

Why Countries Trade?

Countries trade with each other for the same reasons as traders within nations; to get access to goods or varieties not available in other ways and to gain economically from the exchange. International trade induces economic growth when countries produce goods and services in locations where their production requires relatively less resources and effort, and exchange them against products and services that can be produced relatively more efficiently in other countries. Ricardo (1817) first explained how economic gains from trade reflect such comparative advantages in production. The theory of comparative advantage still is valid. Any textbook on international economics explains it (Krugman et al., 2018). Comparative advantage can explain why countries trade different goods. Each country specializes in the goods it produces relatively most efficient and imports the goods produced relative more efficiently by the other country. Ricardo's classical example explains how both England and Portugal gain by exchanging wool for wine (Richardson, 1817). A more modern formulation of the background for such trade was formulated by Venables (2006) as interaction between factor intensity of goods and factor abundance of countries. Thus, countries have comparative advantage in goods that use the factors intensively that the country is rich in.

The theory of comparative advantage explains trade in raw materials such as oil, gas, iron ore, coal, and grain. These commodities are mostly undifferentiated and countries mostly either have access to them and export their excess supply, or need to import them since they are not available at home. These commodities are important cargoes in wet and dry bulk shipping.

A large share of internationally traded goods are different varieties of similar goods or services, for example, the international trade in cars. Thus, a country may both export and import cars. Most countries also exchange tourist travels both having visitors coming to the country and see its own citizens traveling abroad. Such intra-industry trade creates gains for the trading parties by enabling producers to exploit economies of scale in production, and by letting consumers choose different varieties of the goods. This new trade theory was introduced by Krugman (1979). Intra-industry trade explains trade in consumer goods and intermediaries such as parts and components. These goods are the main commodities in air cargo, break bulk shipping and container shipping. The method most widely used to measure intra-industry trade is the Grubel-Lloyd Index (Grubel, 1975).

Krugman (1991) introduced the New Economic Geography that explains localization of the different stages in the production process by combining trade theory and location theory. Production is located and concentrated based on interaction between the internal economies of scale at firm level and the transport costs.

Trade in intermediaries has opened up for fragmentation (Jones and Kierzkowski, 2001) of production lines across countries, thereby increasing international trade and transport. Following this, the share of parts and components in international trade has grown substantially. Several products are assembled from parts and components produced in a many different countries across different continents. Hence, producers outsource parts of the production. This allows for complex division of labor across the world with production of the different parts taking place in their lowest-cost locations. Such organization introduces extra costs of coordination and communication. Deregulation of the airline industry, the development of the telecom industry and the internet facilitated coordination across firms and locations. Fragmentation across locations also increases the transportation content in the final products. Both cost and timeliness of transportation are critical in such fragmented organization of the production.

The volume traded internationally has increased and continues to do so. For the transportation industry, both cargo volumes and trading distance are important, however. Changes in production and consumption locations and thereby in trade patterns may increase or decrease the average transport distance. China's stronger integration into the world economy after joining the World Trade Organization (WTO) in 2001 illustrates the effects on transport distance. China's growing export of consumer goods increased the shipping of final goods in containers to the United States and Europe. This implied both a rise in volume and average distance for container shipping. China at the same time imported more raw materials; oil, iron ore, and later coal, thereby increasing transport volumes and distance especially for the dry bulk fleet. The financial crisis and slower growth in the United States and Europe dampened the growth of these long-distance trades. At the same time, higher economic growth and outsourcing of production from China to emerging Asian economies increased the intra-Asian trade's share of world trade, thereby halting the growth in distance.

Most models in international trade theory, model trade costs including transport cost as so-called "iceberg" cost. Samuelson (1954, p 268) introduced the idea that transportation reduces the value of the goods transported by a fraction proportional to the distance traded. The iceberg formulation of transport costs also implies that valuable commodities are more costly to trade than less valuable goods, when using a fixed percentage of cargo value for transport cost by assuming that transport (iceberg) costs are proportional to cargo value.

How does International Trade Affect Transport?

Ships or aircraft move intercontinentally traded goods, whereas intracontinental cargo flows also move by rail and road. Intracontinental trade resembles regional exchange of goods except for the costs of crossing borders. Intracontinental or regional trade is not discussed in this chapter. Rather, we concentrate on the relationship between international trade and sea and air transportation.

World economic growth and international transportation develop in parallel. Fig. 1 shows the parallel development in world GDP and the volume world seaborne trade.

There is limited overlap or competition between air cargo and maritime transportation. Ships carry heavy bulky cargoes whether wet or dry. Container shipping, however, moves some of the same commodities as air cargo. The freight costs differ substantially between air and maritime transport, and implies limited competition between the two modes of containerized transportation. Air cargo carries commodities that are valuable relative to their weight and especially commodities that also require speed and timeliness. Hence, air cargo consists of time-sensitive perishable and high value commodities. The annual growth in revenue ton-kilometers for air cargo has been 2,6% per year on average in later years. Furthermore, as it is seen from Fig. 2 revenue kilometers performed by air carriers to a large degree reflect changes in industrial production. However, the average growth rate hides big geographical variations (Boeing, 2018).

Containerized maritime transportation over the same years (2007–17) rose by 4.9% per year. The share of containerized cargoes in seaborne trade also increases. This development is consistent with the changes in division of labor in the world economy, where fragmentation has increased trade in intermediaries such as parts and components (Fig. 3).

Efficient Transport Facilitates Trade

Distance is costly. Adam Smith pointed out in *Wealth of Nations* 1776 that international trade relates to location as stronger division of labor and thereby more exchange typically develops along shores and navigable rivers accessible by water transport offering lower transport costs (Smith, 1776).

Hummels (2006) found that roughly half of the volume of international trade takes place between countries located within 3000 km of each other and that regression estimates suggest that doubling the distance halves the volume of trade. Hence, there is a strong relation between distance and trade volume. This distance effect is caused by the rise in transport and communication costs with distance. Hummels (2006) points out, however, that the distance effect has fallen over time. Comparing transport costs for seaborne transport in 1974 and 1998 he finds that the costs difference between long haul (9000 km) and short haul (1000 km) in 1998 was 32% compared to 59% in 1974. For air cargo, the figures were 300% in 1974 and 68% in 1998.

From a similar reason, landlocked countries face higher transport costs for their exports and imports. Economies of scale and the unit load are higher for seaborne transport than for road or rail transportation. Hence, transporting large volumes over land typically is more costly per kilometer than using seaborne transport. In addition, exports and imports from and to a landlocked country face several loading and unloading operations since the cargo must be transferred from one transport mode to another.

The transport intensity for goods differs. For countries which exports or imports transport intensive commodities, the level of transport costs becomes more important in deciding both the volume of trade and where to source imported goods and sell their exported goods. The term transport intensity may also measure the growth in freight transportation relative to the GDP growth. It furthermore, is often argued that the traditional parallel growth between GDP and freight transportation has decoupled in later years. This definition of transport intensity is, however, not used in this section. Here we focus on difference in transportation intensity among different traded goods and services.

High-value transport intensive goods typically move over longer distances than low-value goods as they can better bear the higher transport cost. For high-value products or services, transport costs will imply a lower markup than the similar transport cost for lower value products or services. Hence, high-value, high-quality goods tend to be sent over longer distances. [Hummels and Skiba, \(2002\)](#) studying the relationship between trade costs and the quality composition of trade, found that for high-quality and low-quality units of substitutable products countries tend to export the high-quality variant and sell the low-quality version in the domestic market, since the low-quality version cannot bear high transport and trade costs.

High volume of trade allow for increasing unit loads and thereby better exploitation of economies of scale in the transport sector. Hence, countries with a larger population tend to face lower unit transport costs than smaller countries. Such lower transport costs per unit induce more trade, which by itself leads to a fall in transport costs. This is so as long as there is ample capacity in the transport sector, which enables shipping the extra cargo.

Two-way trade in commodities that moves in the same kind of transport units reduces the imbalance between outbound and inbound transportation and increases the capacity utilization of the transport mode by reducing the share of ballasting in the sailing pattern for the vessels and the air carriers. This is another example of the two-way relationship between transport and trade. Better trade balance reduces transport costs and lower transport costs induce higher trade activity.

Punctuality has become more important following the international fragmentation of production processes and the emergence of just-in-time production strategies in manufacturing. Punctuality is important and more important than speed of transit for most commodities except for fresh and/or time-sensitive products. For such products or services, timeliness is essential. Hence, the quality of transportation services, both transit time, punctuality and low breakage are important for international trade. Thereby, not only the quality of vehicle operation, but also the capacity and the functioning of the infrastructure such as ports and airports, is important for world trade and economic growth. One reason often named for African countries' limited participation in international trade is the general lower capacity and quality of the continents transportation infrastructure.

Trade and Transport Costs Developments

High transport and communication costs hamper international trade. Technological development over the years has facilitated sourcing of goods and intermediaries over long distances. [Jacks and Pendakur \(2010\)](#) assess the effect on international trade from the development in maritime transport following the technological and communicative changes in the 19th century and find that the sharp reduction in transport costs appeared together with the sharp growth in global trade. On average, the freight rates fell 50% and world trade increased 400% between 1870 and 1913. They point out that the development in trade and maritime transport costs were parallel, but falling transport costs did not by itself cause the sharp growth in global trade in this period. Lower transport costs facilitate trade, but growing trade is part both of a virtuous circle of economic growth in the trading countries and of the rising trade between them.

[Hummels \(2006\)](#) gives an overview of the results from several analyses of long-term developments in transport costs in intercontinental trade in the post WWII period, that is, in the development in shipping cost for both air cargo and seaborne trade. By analyzing transport costs as a wedge between prices inclusive and exclusive of transport costs, he assesses the development in transport costs over time. The analysis covers two different price wedges (1) The import wedge assess the price differential between imported goods in the importing country and the price the producer in the exporting country receives, that is, comparing the fob (free-on-board) and cif (cost insurance freight) prices of imported commodities. This wedge does not cover transport costs to and from the border in each of the trading countries and hence does not tell the full story of transport costs for the internationally traded commodities. (2) The sourcing wedge assesses the cost difference for an importer who may import a good from either one of two countries. These wedges are not purely transport costs however. The development in other trade costs may also influence the development in these relative prices over time.

[Hummels \(2006\)](#) cautions the interpretation of these wedges, since the wedge will vary for different goods according for example, to their value and their transportation intensiveness. Some commodities may require higher quality transportation or faster transportation than others may. This has to be considered when analyzing the development in transport costs over time, since the composition of trade changes with time.

Ocean shipping and air cargo experienced substantial economies of scale in ships and aircraft respectively, thereby reducing the cost per ton-km transported. [Hummels \(2006\)](#) finds that overall the transport costs have fallen over time. The freight rates in air cargo have fallen more strongly than freight rates in ocean shipping. The reduction in aggregate transport costs has fallen further

since the composition of commodities in world trade has shifted toward lighter manufactures. Thereby a larger share of goods are shipped by air. Goods shipped by air typically also are more time sensitive than other internationally traded goods. Hence, the development reflects a change in the composition of goods in world trade. There is a reciprocal relationship here, as lower air cargo freight rates increase the distances over which time sensitive goods may be traded.

In 2001 (Baier and Bergstrand, 2001) published an analysis of the growth of world trade among OECD countries between late 1950s and late 1980s with reduced tariff levels, falling transport costs and convergence in income between countries as explanatory variables. They find that income growth is most important for increasing trade with tariff reductions as the number two element. Income convergence on the other hand had no significant effect for world trade growth in their analysis. Declining transport costs also had a significant effect, but markedly lower than the others.

We thus find that there is a close relationship between international trade and transport.

Introduction

There is a vast array of industries, which are sometimes deemed to comprise the global maritime sector. This could include an extremely diverse range of activities from aquaculture and fishing to offshore technology and pipelines (Walters and Bailey, 2013). The field of maritime economics, however, is specifically concerned with shipping as a mode of transportation for the carriage of goods and, to a lesser extent, passengers. In addition to the shipping industry itself, the field also encompasses numerous other activities, which have a direct effect upon the act, or price, of providing shipping services. The most important of these is undoubtedly the port industry, representing another major element of what constitutes the field of maritime economics (Cullinane and Talley, 2006; Talley, 2017). Also included, but to a lesser extent, are: the ship construction and demolition industries; maritime law, finance and insurance; ship broking; and a large number of ancillary activities associated with the replenishment of ships (ship agency, marine fuels, etc.).

Focusing specifically on the shipping industry, it comprises a number of sub-sectors, or market segments, which are ultimately differentiated from each other on the basis of the form of cargo or loading unit carried and the type of vessel design that facilitates the carriage of that cargo or loading unit. Thus, at an aggregate level, the two largest^a sub-sectors of the shipping industry are the *bulk* and *container* sectors. The former is recognized as having a market structure that is very close to perfect competition. However, some form of cooperation remains an important attribute of the latter, suggesting a market structure that historically has been tantamount to oligopoly (and, arguably, still remains so in some parts of the world) and all that this implies about the potential for collusive behavior (Cullinane, 2005, 2011).

This very broad dichotomous market segmentation can be further disaggregated into more specific sub-markets, each defined by their own individual set of characteristics. In general, however, the demand (from shippers of cargoes) and supply (from shipowners or operators) in virtually all shipping markets is characterized by a proliferation of private sector actors, with market structures having largely evolved organically over time as the outcomes of accumulated decisions and actions taken by private sector interests. As a consequence of this, the organizational structures that are germane to the shipping industry (and, to a large extent, also the port industry) are not the product of some grand design. These too have evolved as a response to, or reflection of, market developments. Somewhat inevitably, the skin of these organizational structures hang on the bones of a number of institutions that have developed in order to, variously, moderate the worst excesses of the free market, prevent the abuse of market power, promote free trade, and protect the interests of the many and diverse stakeholder interests at play within the shipping and port markets. The content which

^a In terms of volumes carried, ton-kms moved and revenue earned (i.e., market share).

follows, therefore, addresses the many and varied institutions which are relevant to maritime economics and which help to define its main organizational structures.

Regulation

The International Maritime Organization (The IMO)

By virtue of its inherently international nature, the shipping industry is primarily regulated at a global level by the [United Nations International Maritime Organization \(the IMO\)](#), which is ultimately responsible for ensuring both the safety of life at sea and the protection of the marine environment. In respect of the former responsibility, the IMO is supported by the work of the United Nations International Labor Organization (the ILO) in the setting of appropriate labor standards ([Branch, 2014](#)). Although many international maritime treaties had already been agreed between nations throughout history, the concept of an international organization to regulate the world's shipping industry emerged at the time the United Nations was initially created in 1948. It took until 1958, however, before the precursor of the IMO, the Inter-Governmental Maritime Consultative Organization (IMCO), was inaugurated. This organization subsequently changed its name to the IMO in 1982.

With its headquarters in London in the United Kingdom, the membership of the IMO comprises the national governments of most countries in the world. Over the years, the members of the IMO have ratified a number of conventions that have been converted into detailed technical sets of regulations, which govern the safety of ships and seafarers at sea and protect the marine environment.

The regulations that are ratified by the members of the IMO usually become embodied within a wider pre-existing convention, but can lead to the establishment of a completely new convention or code. The most relevant of these conventions or codes are as follows:

- the safety of life at sea (SOLAS)
- the avoidance of vessel collisions at sea (COLREGS)
- the allowable safe loadlines for ships under different conditions (LOADLINE)
- the reduction of marine pollution (MARPOL)
- the security of ports (ISPS Code)
- ensuring the appropriate management of ships (ISM Code)
- ensuring uniform standards of competence for seafarers (STCW)

In recent years, the IMO has very much focused on the environmental footprint of shipping. The IMO's responsibilities with respect to reducing pollution from ships are dispensed through its Marine Environment and Pollution Committee (MEPC), which also deals with reducing the greenhouse gas emissions of shipping and the industry's contribution to climate change, all of which have been addressed as relatively recently developed elements of the MARPOL convention.

From the perspective of the IMO, it is vital that shipping operates on the basis of globally uniform regulations; any local or regional deviations potentially result in regulatory conflicts, commercial distortion and administrative confusion that undermines the efficiency of shipping and, ultimately, international trade and the economic well-being of nations.

National Maritime Administrations

As implied by the fact that the membership of the IMO comprises national governments that propose, lobby for and eventually ratify regulations which impact the shipping industry globally, it should come as no surprise that those self-same governments have the main responsibility for enforcing IMO regulations within their national boundaries (including their territorial waters). This role is usually undertaken on behalf of the national government by some sort of national maritime administration, which may or may not be a part of the government or the civil service of a nation. Although the nature and name of such entities vary between countries and over time, one defining characteristic is that it administers the national register of ships and ensures that all the IMO's safety, environmental, and other international regulations are adhered to by all ships flying the national flag, irrespective of the country of residence of the shipowner or operator. As such, this responsibility is said to rest with the "flag state" and is sometimes referred to as "flag state control" ([Cullinane, 2010](#); [Branch, 2014](#)).

National maritime administrations also dispense their responsibilities through the implementation of "port state control," whereby ships flying other flags can be inspected when calling at any of the nation's ports – in order to ensure they are compliant with the international regulatory regime. Failure to meet the required standards can result in the detention of the vessel.

In implementing both flag state control and port state control, the national maritime administrations will rely heavily upon the technical expertise of marine surveyors that may be employed directly, but are more likely to be contracted from specialist organizations called Classification Societies that provide a service that validates all aspects of the quality of a vessel. The Classification Societies are fundamentally in competition worldwide for this sort of work, but twelve of the companies involved in the market (covering a 90% market share) do come together under the auspices of the [International Association of Classification Societies \(IACS\)](#) for the purpose of joint representation.

Supranational Organizations

In certain parts of the world, individual nations may be a member of a supranational political and/or economic entity (i.e., a bloc or union) and in some of these cases, a certain level of agreed authority and responsibility for shipping matters is exercised by the supranational entity. By far the most important of these is the EU, not only because of the particular legislative powers it holds over maritime matters, but also because of the economic power of the region and the prevalence of shipping in facilitating its trade, both externally and internally.

Much of the work on the development of the EU's maritime regulations is conducted by the [European Maritime Safety Agency \(EMSA\)](#) as one of the EU's decentralized agencies ([Walters and Bailey, 2013](#)). Based in Lisbon, EMSA was originally established as part of the political response to the Erika (1999) and the Prestige (2002) shipping accidents, where the resulting oil spills caused significant problems along the coasts of France and Spain. EMSA now provides technical assistance and support to the European Commission and individual EU Member States in the development and implementation of EU legislation on maritime safety, pollution by ships and maritime security. It also has operational responsibility in the region for oil pollution response, vessel monitoring, and the long-range identification and tracking of vessels.

There is no denying that the regulatory authority exercised by the EU in the maritime arena has sometimes brought it into conflict with the IMO, particularly in relation to environmental issues. In the past, the same was also true of the national government of the United States. Despite the problems that the non-uniformity of shipping regulations across the globe brings to shipowners and operators, the influence of the EU's role in such matters (as similarly was said of the United States) is widely perceived as having prompted the IMO into the implementation of appropriately more stringent regulations and speedier implementation.

Supply-Side Structures

Shipowners Associations

In nearly all of the major maritime nations, individual shipowners and operators (i.e., third party managers) are typically members of a national "Shipowners Association" which represents the interests of the national shipping industry in lobbying national maritime administrations and/or the government. Such associations also help to protect the interests of their members in relevant international fora ([Cullinane, 2010](#)). However, each national association is, in turn, likely to be a member of a supranational association representing the combined interests of a number of national shipping industries *en masse* within a particular area of the world. In the case of the EU and Norway, the [European Community Shipowners' Association \(ECSA\)](#) was founded in 1965 with a mission to promote the interests of the European shipping industry.

ECSA and other supranational associations represent a middle tier in a large pyramid structure of representation to which shipowners and operators have access. Sitting at a higher level again, the [International Chamber of Shipping \(ICS\)](#) is the world's largest organization representing the interests of shipowners and operators, having a membership of national, and other supranational, associations that together accounts for more than 80% of the world's total tonnage of merchant ships. The ICS concerns itself with the full range of regulatory, operational, and legal issues that affect shipowners or operators and has a role as a consultative body at the IMO, as well as with the other intergovernmental bodies which are relevant to the shipping industry; for example, the [World Customs Organization \(WCO\)](#), the [International Telecommunications Union \(ITU\)](#), the [United Nations Conference on Trade and Development \(UNCTAD\)](#), and the [World Meteorological Organization \(WMO\)](#). The ICS also maintains a close working relationship with a number of other trade associations that represent maritime interests, such as ports, pilotage, the oil industry, insurance, and classification societies.

The ICS claims to be unique in representing the global interests of all the different forms of shipping, encompassing the various ship types that operate within the different specific shipping markets. As this implies, there exist a number of other trade associations within the maritime arena that represent more specific interests that are usually aligned either with a particular form of cargo or a particular shipping market.

Intertanko

[INTERTANKO](#) (the International Association of Independent Tanker Owners) came into being in 1970 as a trade association representing independent tanker owners and operators at national, regional, and international levels. It has a mission to develop and disseminate best practice within the sector, in order to promote safer, cleaner, and competitive tanker operations in support of global oil, gas, and chemical product networks. This necessarily involves taking a lead on the development, acceptance and implementation of uniform, worldwide international tanker standards. In an effort to counter what is perhaps a negative public image, it also plays an important role in promoting the tanker industry by communicating its role, strategic importance and social value to both stakeholders and the public. In so doing, as a recognized non-governmental organization, INTERTANKO has a consultative role with the IMO, UNCTAD, and the [International Oil Pollution Compensation Funds \(IOPC\)](#). It also has a close working relationship with several other relevant organizations, such as the [Oil Companies International Marine Forum \(OCIMF\)](#), the [Chemical Distribution Institute \(CDI\)](#), the [Society of International Gas Tanker and Terminal Operators \(SIGTTO\)](#), the [International Association of Class Societies \(IACS\)](#), the [International Group of P&I Clubs](#), and the various maritime administrations involved in the regulation of the shipping industry.

Intercargo

Established in 1980, **INTERCARGO** is the short name for the International Association of Dry Cargo Shipowners and was created to represent the interests of a membership that primarily operate bulk cargo ships (i.e., bulk carriers) in the international dry bulk trades, such as coal, grain, iron ore, and other bulk commodities. The association seeks to achieve a safe, efficient, high quality, environmentally aware, and profitable dry cargo shipping industry within the context of free and fair competition within the market. It seeks to achieve this through the development of strategies, which enhance the interests of its members for the benefit of the dry cargo shipping sector as a whole. Much of its work toward meeting its objectives involves participation on a consultative basis at the **IMO** and, in order to avoid the costly and inefficient duplication of time and effort, close collaboration with other shipowners associations, such as the **ICS**, **ECSA**, etc. This latter is facilitated through a "Round Table of International Shipping Associations."

World Shipping Council (WSC)

The bulk-shipping sector (both wet and dry) constitutes one of the two main shipping sub-markets. The other major shipping market sector is the container-shipping sector. The interests of shipowners operating in this market are represented by the **World Shipping Council (WSC)**, the members of which comprise the world's major container (liner) shipping companies, accounting for approximately 90% of the global liner vessel capacity. The WSC was originally formed to represent the interests of the international liner shipping industry in discussions with the US government in relation to the reporting of freight rates (prices). Following the 9/11 terrorist attacks, however, the priority of the WSC became ensuring the security of international maritime commerce and the supply chains that trade depends upon, without impeding the free flow of commerce. In so doing, it forged close working relationships with the US government and the European Commission and is now based in Brussels. Its contemporary remit is to cooperate in the development of new laws, regulations and program, which are designed to enhance trade, security, the efficiency of customs procedures, and the environment, with respect to the international movement of containers. The WSC is also heavily involved in developing the laws on cargo liability and the use of IT in facilitating customs procedures for containers. These efforts are facilitated by the WSC having consultative status with the IMO as a recognized non-governmental organization. Particularly since many of its members are also the owners or operators of ports or port terminals, trucking companies, and other transportation modes, the WSC also involves itself on a worldwide basis in the development of adequate and efficient transportation infrastructure capacity.

Alliances

Aside from the formal representational role performed by WSC on behalf of container (liner) shipping companies, some form of cooperation between companies operating in this market has been a common feature of how the market operates. The precise form of cooperation has varied over time and in different geographical regions and, as a consequence, specific terms have evolved to define a certain form of cooperation. The most traditional form of cooperation takes the form of a liner shipping conference, which harks back to the 19th century and certainly, therefore, predates the containerization era. The conference system revolves around the cooperation of shipping companies operating on a specific liner trade route (usually defined in a single direction) agreeing to a predetermined tariff for the provision of shipping services. As such, many shipping companies were simultaneously party to multiple conference agreements; depending upon which routes they operated on. Due to concerns over the abuse of market power, in many parts of the world the conference system has been effectively outlawed, although it does continue to prevail in some parts of the world, notably in certain intra-Asian trade routes.

In the absence of the conference system, in an effort to preserve some form of cooperation between container (liner) shipping companies, at least at the strategic level if not operationally, a number of forms of cooperative arrangements have emerged over time. Having moved fairly swiftly through an era of container shipping consortia, we are now in an era where the shipping alliance (or ocean alliance) holds sway. This is a form of agreement where a number of container shipping companies join forces in global strategic cooperation across the various trade routes where they are jointly involved. In effect, the alliance plays exactly the same role as an individual container shipping company, but provides greater network coverage and scope. However, the individual shipping companies that constitute the membership of an alliance do remain firmly independent from each other; commercial information on cargoes, freight rates (prices), customer information etc, is not shared and arrangements between individual companies (lines) and land-based entities, such as terminals, hauliers, depots, CFS, etc. remain strictly confidential to the contractual parties involved.

Although some competitive concerns still remain about the nature of the shipping alliances, the logic underpinning their existence is that it is only by sharing resources in the form of ships, terminals in ports, and networks, that they can provide the level of shipping capacity required by the market demand. The global cooperation offered by being part of an alliance means that the variable costs of providing shipping services can be reduced to an extent that facilitates the optimal deployment of ship capacity within the container shipping networks in which a specific alliance operates. As such, the presence of alliances appears to be closely associated with fueling the development of mega-container vessels and mega-terminals to handle their cargoes. This has allowed the reaping of economies of scale in both ship and terminal operations, especially since alliances are then in a position to negotiate better tariffs at ports and push for volume discounts. These cost savings not only allow the member companies to stay competitive but also, it is argued, they can even be passed on to customers, thus refuting any possible allegations of the abuse of market power.

The deployment of ever-larger vessels to service the container trades and the responses that terminals have been forced to make in expanding their facilities, together with a tendency toward the concentration of the market via merger and acquisition activity, all point to the likely persistence and evolution of the strategic alliance model in container (liner) shipping.

The Demand for Shipping - Cargo Interests

There is no inherent desire to consume the services offered by transportation companies. The demand for shipping comes purely and simply from the demand that exists to consume the products, which are carried on ships. Thus, the demand for shipping services is defined as a “derived demand.” The ultimate source of this derived demand comes from the manufacturers, wholesalers, and retailers (collectively referred to as “shippers”) that are selling products to buyers (presumably, in order to make profits) where transportation by sea is required. In some cases, the shippers of products employ intermediaries such as freight forwarders; third party logistics service providers (LSPs) or other types of agent in order to make decisions about or to facilitate the transportation of freight. For the purposes of what follows, the all-encompassing term “shippers” can be interpreted as potentially including these agents.

Regional (Supranational) Shippers' Associations

The interests of manufacturers, wholesalers, retailers, and their agents are often represented by shippers' associations. These can and do exist at national level, but because of the multinational presence of many of these sorts of companies and the nature of international container (liner) shipping companies, regional (supranational) shippers' associations provide a more significant organization as the basis for shipper representation (Branch, 2014). The most important shippers' associations are the Asian Shippers' Alliance (ASA)^b, the [European Shippers' Council \(ESC\)](#), and the [American Association of Exporters and Importers \(AAEI\)](#). The members of regional shippers' associations comprise national shippers' associations, commodity trade associations and individual shippers who are bound together through a desire to ensure the safe delivery of their products to their customers in the right condition, at the right time, at the right price, and in the most efficient and sustainable way.

The existence of shippers' associations goes back a long way and is perceived to have significant advantages for not only shippers, but also for shipowners and operators. The most significant of the perceived advantages is the securing of low costs to members through the consolidation of purchasing and bulk buying on members' behalves. This process of consolidation has the additional benefit of increasing the buying power of smaller shippers. Other advantages are: rate stabilization and less transactions-based negotiations; reduced administrative burden on individual shippers through centralization; the use of structured agreements which facilitate members having access to more carriers and providing shipping companies with a larger pool of potential customers; easier compliance with the relevant regulations for both shippers and carriers; the sharing of market intelligence and; the use of common carriage terms and conditions, rather than on a contract by contract basis. The different regional shippers' associations have slightly different regional concerns, which are reflected in their activities. As just one example, the ESC seeks to help its members take maximum advantage of the internal European market and has vocal input into policy debates on the restrictions on the weight and dimensions of lorries, the hiring of personnel across EU member states and differences between the implementation of VAT and excise duties between EU member states.

The Global Shippers' Alliance (GSA)

The [Global Shippers' Alliance \(GSA\)](#) consists of the ASA, the ESC, and the AAEI. Its objective is to promote the beneficial evolution of regulations, markets and best practice to enhance trade and the flow of goods across the globe. It seeks to achieve this through the appropriate dissemination of information and knowledge, by facilitating better understanding between shippers and ocean carriers and by liaising with national and international authorities on maritime issues.

Ancillary Institutions

Having identified the major organizations and institutions involved on both the supply and the demand side of the overall shipping market, it is important to identify a number of other key players which have a role in facilitating the workings of the shipping markets.

UNCTAD

With its headquarters in Geneva in Switzerland, the [United Nations Conference on Trade and Development \(UNCTAD\)](#) was established in 1964 as a permanent intergovernmental body. Its purpose is to help developing nations overcome the difficulties faced in reaping the benefits from international trade. Recognizing the benefits that greater international trade has brought to

^b At the time of writing, the Asian Shippers' Alliance (ASA) does not have a website.

the world, UNCTAD is intent in ensuring a more equal distribution of those benefits (Cullinane, 2011). In its efforts to do so, UNCTAD has been pivotal in identifying the importance of transport costs and maritime connectivity in the facilitation of, and participation in, international trade, and the economic growth, which ensues from this. Working at the national, regional, and global level, this has then led to initiatives, which help to overcome the disadvantages faced in these respects by the developing world. These have encompassed the need for investment in appropriate transport infrastructure, a focus on greater efficiency in the use of infrastructure and the need for better governance structures in the management of that infrastructure; all of which have the intention of reducing the costs of maritime transport to and from developing nations and/or speeding the flow of goods. At a more structural level, UNCTAD also pursues the objective of helping developing nations move their production further up the supply chain and this too has implications and knock-on effects for its trade and the maritime transport which services it.

The Baltic Exchange

All contracts of carriage that are agreed between a shipper and a shipowner/operator contribute in some way to the current state of the shipping markets. That market may be defined very specifically in terms of a cargo or loading unit, a route and a size of shipment or, at the highest level of aggregation, as simply the bulk or container shipping market. Although some contracts of carriage are agreed directly between a shipper and a shipowner/operator (particularly in the liner trades, where containers are merely booked directly onto ships), some contracts of carriage are struck with the help of an intermediary shipbroker (particularly in the bulk trades), who may or may not be a member of a professional association called the [Institute of Chartered Shipbrokers](#), but who will almost certainly be a member of the [Baltic Exchange](#). The membership of the Baltic Exchange is responsible for a large proportion of all agreed contracts of carriage for bulk cargoes (both wet and dry), as well as the sale and purchase of merchant vessels. In all cases, the detail of the contract, particularly with respect to the agreed contract price, provides interesting and potentially useful market information to players engaged in the market (Stopford, 2009).

With its origins going back to 1744, the Baltic Exchange is based in London, with regional offices in Singapore, Shanghai, and Athens. Its membership of over 650 companies encompasses the majority of the world's major shipping players that, as members, adhere to a code of business conduct overseen by the Baltic Exchange and which is embodied in the institution's motto, "our word, our bond." With the access its members have to data on the deals agreed, primarily in the bulk shipping markets, the Baltic Exchange is in the position to aggregate this information and to disseminate it in a manner, which does not breach commercial confidentiality. As such, the Baltic Exchange is the world's leading, and only independent, source of maritime market information on the trading and settlement of both physical and derivative shipping contracts. Based on assessments made by a global panel of shipbrokers, the Baltic Exchange provides daily freight market prices and maritime shipping cost indices for a range of global shipping markets which are used as a guide or benchmark for the setting of freight rates (prices) in ongoing negotiations of contracts of carriage, as well as a settlement tool for freight derivative trades and as a general indicator of the bulk market's performance.

BIMCO

The nature of any contract of carriage agreed between a shipper and shipowner/operator will vary between particular shipping markets. In the majority of cases, the terms of the contract will be dictated by specific market characteristics and, as such, the detail contained within a specific market contract will not vary that much from deal to deal. As such, [BIMCO](#) has a major role in designing, updating and disseminating standard contract forms for use by the industry. When concluding a deal, either directly or via a shipbroker, the relevant party will start with the standard form for a contract of carriage for that specific shipping market and contract type and then edit it to encompass the fine detail as agreed between the shipper and shipowner/operator, most especially concerning the price and/or any tailored clauses that need to be included (Cullinane, 2010).

Biography

Kevin Cullinane is Professor of International Logistics and Transport Economics at the University of Gothenburg. Kevin has been a logistics adviser to the World Bank and transport adviser to the governments of Scotland, Ireland, Hong Kong, Egypt, Chile, and the United Kingdom. He holds an Honorary Professorship at the University of Hong Kong and is a visiting Professor at the VTI (the Swedish National Road and Transport Research Institute), Liverpool John Moores University, Dalian Maritime University, and Shanghai Maritime University. Prior to joining the University of Gothenburg on a permanent basis, he was appointed to the lifetime position of Honorary Visiting Professor at the University. Kevin has personally won research and consultancy projects to the value of \$US 6.5 m, many of which have informed the policies of national and/or regional governments. He has held other positions as the Director of the Transport Research Institute (TRI) at Edinburgh Napier University, Chair in Marine Transport and Management at Newcastle University, Professor and Head of the Department of Shipping and Transport Logistics at Hong Kong Polytechnic University, Head of the Center for International Shipping and Transport at Plymouth University, Postdoctoral Research Fellow at the University of Oxford Transport Studies Unit, and as Senior Partner in his own transport consultancy company, based in Cairo, Rennes, Hong Kong, Edinburgh and now Gothenburg. In terms of academic outputs, Kevin has published 14 books and over 300 journal papers and is an Associate Editor of *Transportation Research D*, *Maritime Economics & Logistics* and the *International Journal of Applied Logistics*. He is also a member of the Editorial Boards of *Transportation Research A*, *Transport Reviews*, the *Annals of Maritime Studies*, the *Journal of Shipping & Logistics* and, formerly, of the *Proceedings of IMechE Part M: Journal of Engineering for the Maritime Environment* and the *International Journal of Logistics Management*. Kevin has been a Chartered Fellow of the Chartered Institute of Logistics & Transport since 1997. His expertise has been recognized at UK national level with his appointment to REF 2014 and REF 2021; the UK's national research evaluation exercise.

Introduction

Seaports, hereafter ports, are interfaces between maritime transport and land transport. That is, ports connect these two modes of transport by providing services to the two broad groups of stakeholders. Ports facilitate trade and industries, which in turn contribute to a country's economic and social development. These fundamental roles performed by a port reflect the fact that port development affects not only the surroundings of a port, but also regional development as a whole. As such, a port is a critical coastal infrastructure which requires careful planning. The nature of this transport sector is capital-intensive, hence a key topic in port studies is port investment. This article aims to illustrate the fundamental concepts in port planning and investment. It will also discuss new trends in practice related to port planning and investment.

Port Planning Aspects

From infrastructure and physical connectivity's point of view, port planning can be broadly categorized into three aspects, namely seaward, terminal, and landward planning as summarized in **Fig. 1**. This section explains the three port planning aspects with examples from the port industry.

Seaward Planning

Seaward planning refers to all matters related to a port's maritime access in the harbor or port limit. Being an interface servicing ships, the scope of seaward planning covers infrastructure, facilities and services for ships and shipping, which include those for international ships (ocean-going vessels) and domestic ships (e.g., ferries, tug boats). This pertains to navigation channels (also known as fairways), navigation aids, locks, anchorages, pilotage, towage, breakwaters, bunkering, and shipyards. It can be seen that seaward planning entails a large spectrum of activities requiring highly specialized skills and knowledge. In fact, each activity can be considered an industry sector by itself or a subsector under the maritime industry ecosystem. For instance, bunkering is a sector for refueling ships; pilotage is a sector for guiding and navigating ships in domestic port waters.

In most ports, the entity overseeing the seaward planning is a country's maritime or port administration, such as a maritime authority. Service providers and operators can be a government organization, public enterprise or private enterprise. For example, in the case of Singapore, the Maritime and Port Authority (MPA) of Singapore, under the Ministry of Transport, is a government statutory board acting as a port planner. Navigation channels, navigation aids, anchorages, and breakwaters are provided and maintained by MPA. Pilotage, towage, bunkering, and shipyard services are provided by private companies.

Terminal Planning

Another aspect of port planning is terminal planning which refers to matters related to shore-based terminal areas. At an aggregated level, terminal planning considers strategic location selection and terminal layout design. The major components of terminal planning include berthing, loading and unloading system, storage yard, and gate system. From the planning perspective, berthing consists of quay and berth design, vessel information management, and berth allocation policies. A loading and unloading system involves stowage plan and cargo handling equipment allocation and scheduling. For storage yard planning, yard configuration,

Figure 1 Three aspects of port planning and respective components.

cargo information management, as well as cargo handling equipment allocation and scheduling are required. A gate system planning includes receipt and delivery facilities, safety and security control policies, and intermodal transport connections. The four major components of terminal planning should be coherently designed to facilitate smooth terminal operations. This is the concept of integrative terminal planning. Thus, the various parts of a terminal should be well linked so any part would not become a bottleneck pulling down the terminal's performance.

From cargo's perspective, terminal planning has to cater to the characteristics of different cargo types. These include dry bulk, liquid bulk, gas and chemicals or other dangerous goods, breakbulk, general cargoes, perishables, roll-on roll-off cargoes (i.e., vehicles), project and special cargoes, as well as unitized cargoes mostly in containers. The cargoes can be very distinctive in nature, hence their handling and operating procedures are specialized. Cargo types affect every component of terminal planning as explained above. For example, berth design, cargo handling equipment, and storage facilities are all different for a dry bulk cargo terminal when compared to a liquid bulk terminal.

In terms of the party who manages terminal planning, there are various approaches in different ports due to different port ownership and governance models. The landlord model is popular in which a country's government owns the land while port superstructure, facilities (e.g., office buildings, warehouses, and cargo handling equipment) and operations are provided by a terminal operating company. The terminal operating company can be a state-owned enterprise, private firm, or hybrid entity or consortium such as joint-venture of a public organization and a private firm, that is public-private partnership (PPP) (Xiao and Lam, 2020). Therefore, quite a number of variations exist in port ownership within the landlord model. Using the same example as stated earlier, MPA of Singapore is in charge of the overall infrastructure aspect of terminal planning in Singapore while two terminal operating companies—PSA Corporation and Jurong Port Private Limited manage and operate the container terminals and multi-purpose terminals, respectively. Other ports using the landlord port model are Antwerp, New York, and Shanghai, to name a few examples. Because this article does not focus on port ownership and governance, readers are referred to the list of further reading to have a better understanding on this subject matter.

Landward Planning

Landward planning covers all issues related to a port's inland distribution and connectivity. This aspect extends from the gate system in a terminal to a port's foreland and hinterland. Ports should be well connected with maritime transport on one hand and inland transport on the other hand. For inland distribution, a port can interface with various modes of transport, including road, rail, inland waterway, air transport, pipeline, and a combination of these modes, that is intermodal transport. Associated distribution and logistics services are attributed to a port's performance. Inland transport operation is beyond the scope of a port per se, but the planning aspect is essential in order to ensure the port's accessibility. Effectively inland connectivity should be analyzed right at the start of any port planning, and it even affects the feasibility of a new port's location. Landward planning also includes the scope of freight corridors linking to industries where the cargo sources are located. Furthermore, port planning affects urban planning, or port planning is part and parcel of urban planning. Many ports and coastal cities are intrinsically linked. Planning includes, for instance, concerns on optimizing land use in view of competition for space from various sectors in an economy; codevelopment of a port and a city where the port is located (Lam and Yap, 2019).

Due to the reason that the scope of landward planning is wide and beyond the port itself, parties involved usually come from multiple organizations. That is, landward planning requires multiorganizational efforts. A country's maritime or port administration, such as a port authority may act as an overall coordinator to work with various parties including land transport authority and urban planning authority. They could jointly devise plans to develop a sustainable port city for the city and the port to support each other. Regarding service providers, typically public and private enterprises operate inland transport and logistics. For example, there are many private firms being trucking companies and third-party logistics service providers servicing port users in majority of ports in the world.

Connecting the Three Planning Aspects

Although the scope of the three aspects of port planning is very diverse, they should not be treated in isolation. The physical flow of a cargo ship calling at a terminal is briefly described here to outline how the various port planning aspects and elements are connected. When a ship enters a port through its navigation channels, the ship sails to the berth that is allocated. Depending on the port's regulation, pilotage services may be mandated for a marine pilot to navigate the ship. Before berthing, the ship may have to wait at the anchorage area if there is no available berth due to reasons such as congestion. Once a berth becomes available, the ship is towed toward the berth by a tug boat. While approaching the berth, quay cranes (or other suitable cargo handling equipment according to the cargo type) are allocated to the ship based on the volume of cargoes on board the ship to be loaded and/or unloaded. The process of cargo loading and unloading starts after berthing. For inbound cargoes, that is import, the cargoes will then be transferred to the yard area for temporary storage on the terminal before they are collected by consignees and leave the terminal for their destination, for example industrial sites. For outbound cargoes, that is export, cargoes come from the hinterland and arrive at the terminal. The cargoes will be transferred to the yard area for temporary storage before they are loaded on the ship for onward shipment. After cargo loading and unloading is completed, the ship will leave the berth, sails through the navigation channels and leaves the port eventually. Similar to ship arrival, pilotage and towage services may be required between the time of un-berthing and leaving the port limit. In the process, bunkering and other marine services like replenishing ship supplies could be performed at the same time when the ship is anchored or at berth. In other words, two or more marine services may be performed concurrently while cargo handling operation is conducted. For such cases, very good coordination among service providers is needed to ensure efficient and safe operations.

In addition, the role of ports in supply chain management has drawn growing interests in the industry. Ports are key nodes in supply chains linking various port operators, users and stakeholders including shipping companies, marine service providers, terminal operators, inland transport providers, government authorities, and urban planners. Therefore, the various port planning elements should be integrated to enable efficient physical flows and information flows. Port planning is required to take care of diversified interests of various parties, leading to its complexity. On one hand, it is a challenging task especially dealing with conflicting interests from different stakeholders. On the other hand, this can be regarded as an opportunity to differentiate from competing ports (Lam and Li, 2019). A port which is able to find win-win solutions will create and sustain value for port stakeholders, leading to a strategic competitive edge.

Therefore, port planning is a multifaceted process which entails technical issues, economic development, financial matters, environmental issues, political issues, legislative processes, urban planning, and stakeholder management. The overall environment faced by ports is constantly changing. Port planning is vital to the long-term success of a port, and it is also dynamic with various perspectives to be considered during the process. As a consequence, port planning should evolve in response to the changes and help a port to be competitive.

Port Planning and Development Process

After illustrating the three port planning aspects, this section explains the planning process and considerations of developing a new port, expanding or upgrading an existing port. This is also known as a port master plan. As a starting point, the objective of a port planning and development project should be identified. Then the planning process is designed to cater to the interests of different stakeholders as well as the development of the local economy.

1. Existing demand, supply, and pricing

Similar to any economic framework, demand, supply, and pricing are basic elements determining port planning and development. Existing demand of a port indicates the current traffic volume needs to be handled in the port, based on data such as cargo, passenger, and vessel statistics. Existing supply is the capacity already being built to accommodate and handle demand, usually depending on the capacity of infrastructure and superstructure. Analyzing demand and supply data helps to find out if there is imbalance between the two elements. A port should also review the current pricing structure to assess if any changes are required. Pricing measures can be used as a short-term solution to influence customer and supplier behavior. As for medium to longer term, insufficient supply or increasing demand can trigger the need for port development, for example, upgrading or expanding a terminal to have additional capacity to handle more ship calls.

2. Performance indicators

Port performance statistics could be generated from current demand and supply data. This indicates the performance of a port in a specific and quantitative manner, referring to the matching level of demand and supply. Some examples of port performance statistics are ship turnaround time, ship waiting time, berth utilization rate, and truck turnaround time. Performance statistics also implies the productivity level and trend of a port, which is then used to derive future demand and align with corresponding supply. Also, performance indicators reflect whether the service quality of a port has met the desired level as set by port managers and areas for improvement when needed. The information is important for identifying port planning and development projects in next steps.

3. Traffic evolution

Traffic evolution, of which data could be derived from cargo, passenger and vessel statistics, is an important factor driving the development of a port and should be considered in a port plan. In general, potential changes in production, market, trade, goods

or cargoes, and shipping lead to different trends and will influence traffic evolution (Yap and Loh, 2019). These include trends in commerce or trade patterns, trends in shipping, trends in physical appearance of goods, and trends in cargo handling. The rationale behind is that shipping is a derived demand and ports are built to support shipping activities. Future developments in trade, shipping and products will alter the demand and traffic patterns of a port. Hence, port expansion or alternation works may be required. However, a port may face competition from other ports so developments in other ports should be taken into account.

4. Development plan

On the supply side, based on the current condition and limitation in capacity of infrastructure and superstructure as well as the future desired supply capacity, a port development plan will be proposed. It is important to note that the plan should be aligned with a port's long-term goal and strategy. For instance, whether a port aims to attract transshipment traffic or mainly focus on local hinterland traffic significantly affects a development plan. At the same time, constraints and limitations faced by the port should be examined. Inherent limitations such as scarce land and resource, as well as regulatory requirements such as government policies should also be taken into consideration. A draft port development plan should go through cost and benefit analysis. After a new development plan is clearly defined, the objectives of port planning are more detailed, including capacity planning which serves as an important guide during construction. Specifically, four essential components including alternative design, financial considerations, environmental considerations, and regulatory requirements are the key determinants. They will be elaborated as follows.

5. Alternative design

This is more of a construction and engineering aspect with considerations of geography, ship–shore interface, and types of ship, cargo and passenger. Related to the above-mentioned aspects of port planning, the scope of design could be the configuration and layout of a navigation channel, harbor basin, terminal area and foreland/hinterland connection. Geotechnical and natural conditions such as coastal environment, soil, wave and weather are included in the feasibility assessment of alternative designs. For long-term development of a port, potential expansion in the future should also be accounted for.

6. Financial analysis and investment plan

Thorough financial analysis consisting of capital cost, operating expense, return on investment, infrastructure and superstructure maintenance cost, cash flow, etc. is an integral step in port planning. Simultaneously, an investment plan is required to explore and examine options of funding port projects and how to utilize suitable financial instruments such as taking loans, issuing bonds, and seeking government subsidies. Funds may be sourced from the public sector, the private sector, or a mix of the two sectors in terms of a PPP. Also, funds may come from local sources or foreign investors. In most cases, the mode of investment and imposed conditions depend on the ownership model of a port which is established by the government.

7. Environmental Impact Assessment and other regulations

Environmental considerations should also be emphasized. With reference to the Organisation for Economic Co-operation and Development (OECD), negative environmental impacts include noise, waste, emissions of particles, greenhouse gas and pollutants, and dust caused by handling substances such as grain, sand and coal (Braathen, 2011). For example, reclamation and dredging work in a port to expand port capacity can greatly affect the ecosystem on which the marine lives rely. In addition, road and rail traffic connecting from a port to hinterland also generates pollution. Therefore, Environmental Impact Assessment, usually including elements such as Initial Environmental Examination and Environmental Impact Studies, is required by many port authorities or regulators. Approval is required before conducting any port projects.

There could be other regulations that port planners have to observe, for example, those related to land use, handling of hazardous substances, port and shipping safety, security, labor, free trade zone, and antitrust law. The appropriate legislative procedures and approvals should be incorporated in the port planning process.

8. Final development project

After various steps are conducted to analyze a port project's feasibility, a port planner should integrate the analysis, consider costs, benefits, and uncertainties of different alternatives holistically, and decide on a final development project. For instance, project timeline, budget, resource, development phases, and other details should be specified.

Trends in Port Investment and Port Technology

Port development demands tremendous amounts of resources and professional expertise that may not be readily available in many port authorities. Port liberalization and privatization started in the late 1970s which have led to the prevalence of the landlord port model. In this port governance model, a government authority owns the land where infrastructure is leased to privately owned companies or a joint venture which is owned jointly by the public sector and the private sector. Therefore, it is a form of PPP which is a contractual form of collaboration between the government and the private sector. The progressive opening of the port sector worldwide presents opportunities for international terminal operating companies to enter into markets of different regions. The port industry also sees shipping companies investing in port projects. These trends are common to both developed and developing countries.

After many years of globalization and liberalization, however, protectionism takes place in some cases such as the withdrawal of the United Kingdom from the European Union, that is Brexit, and tensions between China and USA. These create undesired instability and risk in port investment. For example, USA plans to increase scrutiny of foreign direct investment in the country

from China and other foreign investors including those in seaports, claiming reasons of national security (The New York Times, 2019).

An imperative implication for port planning and investment is the need for a supportive institutional structure beyond a port by itself. A port is a kind of system in a national socio-economic-political system as well as the globalized economic system. As such, port investment matters ought to be considered in the context of structural factors of the overall systems. Port development of a country is determined by the political will of its government. Trade, investment and other policies alike shall continue to play important roles. The port industry is expected to encounter changes and uncertainties, while port investors should actively look for opportunities in growing markets.

A key area of opportunity in the 21st century is technology. It is an essential element in every aspect of port planning and operations. On the demand side, technology is a factor influencing existing demand from shipping and trade; meanwhile, the demand will trigger the development of technology. New technologies also change transport patterns by leading new trends. To cite several examples, bigger vessels increase the cargo volume to be handled and call for higher productivity from terminal operators; autonomous vessels draw the focus to new ways of handling these vessels safely; e-commerce alters consumer behavior and seaborne trade routes; blockchain technology leads to changes in shipping documentation procedures that government authorities and port operators have to cope with. On the supply side, new technologies applied in port infrastructure and superstructure can increase the capacity of a port and create more alternative designs when a port plan is proposed. Advanced technologies are also able to overcome some environmental issues as well as port limitations such as the use of full electric cargo handling equipment drawing from renewable energy sources (Iris and Lam, 2019). Together with port performance statistics and indicators, technology factors also determine productivity trends by affecting vessel and cargo handling performance (Vanelslander et al., 2019). For instance, new quay crane design, a higher level of automation, deploying Internet of things technology like sensors contribute to port productivity.

Furthermore, appropriate use of technology helps a port to become more intelligent. Data and information about vessels, cargoes, customers, assets, and other elements can be analyzed to facilitate decision making. By leveraging on data mining tools, port planners and operators may realize the benefits brought by descriptive, diagnostic, predictive, and prescriptive analytics. For example, an advanced vessel traffic management system is capable of enhancing efficiency in port waters by tracking vessel movement real-time. Collision avoidance and detection of abnormal activities lead to better safety and security of the port. Technologies are rapidly evolving in the contemporary era, those ports which make strategic moves to capture opportunities and create value for users and stakeholders will be well-positioned in the sector.

Conclusion

In times of changing trends of globalization and trade patterns, the port industry and its actors are encountered with higher market volatility and uncertainties. Combining with random shocks like negative impacts on the economy brought by political tensions among countries and pandemic result in complications for decisions in port planning and investment. Ports being very long-term critical infrastructures serve national, regional and even international interests. Hence, port planners and policy makers are recommended to embrace comprehensive strategic planning and innovation to always stay relevant.

Biography

Prof. Dr. Jasmine Siu Lee Lam is Centre Director of Maritime Energy and Sustainable Development Centre of Excellence at Nanyang Technological University, Singapore. She is also Director of Maritime Studies Programme. Her major research areas are maritime and port economics, sustainable development, logistics, and risk management. She has been invited by various organizations, port authorities, companies, and universities as a key speaker at international conferences. Leading a R&D team and working closely with the industry and government agencies, Jasmine has completed over 50 projects including consultancy to many countries and has more than 280 scientific publications including over 130 top-tier technical journal papers. She serves as the editor/board member of 10 international journals, including Maritime Policy & Management as Associate Editor. She is a Global Maritime Technology Cooperation Centres Network Stakeholders' Committee member, invited by International Maritime Organization, and the Vice President of the International Association of Maritime Economists. Furthermore, Jasmine is the recipient of many awards, including Best Paper Awards, Erasmus Mundus Faculty Scholar Award awarded by the European Commission, and National Day Award from the Prime Minister's Office in Singapore.

Introduction

Transport infrastructure (e.g., roads, tracks, and stations of rail and public transport, inland waterways, ports and harbors, airports, and pipelines) plays an important role as capital input into production and the generation of wealth. It is a necessary input for the production of transport services which are in turn necessary for the exchange of final products and inputs and for broader welfare benefits such as travel time savings. For various types of economic analysis, such as productivity and efficiency analysis, cost and production function studies figures on the value of transport infrastructure, for example, the capital stock is a crucial input.

In most OECD countries, estimating the value of capital stocks of industrial sectors is a common procedure, based on the worldwide methodological standards defined within the System of National Accounts (SNA), and within its European equivalent, the European System of Accounts (ESA). Transport infrastructure is covered in different sections of the SNA classifications of assets, institutional sectors, and economic activities. It is mainly included in parts of sections H (transport, storage, and communications) and L (public administration, defense, and social security). This lumping together with other industries and the spread over different subsections of the SNA implies that an overall figure for the capital stock of transport infrastructure is in almost no country available. An exception is the road network for which several OECD countries publish road investments and capital stock values.

In general and not only related to transport infrastructure, measuring capital faces many empirical issues which arise due to the absence of observable economic transactions; they relate to questions such as not only how to measure flows and stocks, but also how to estimate volumes and prices of flows of capital services. In the transport sector, a range of institutional settings such as pure public ownership versus private and mixed public/private ownership adds complexity to the measurement of both investments and capital stocks. Capital stock calculations for transport infrastructure face additional problems due to the long service lives of assets.

As each type of capital, infrastructure capital can be viewed from two sides, from the income and wealth perspective, and from the production and productivity perspective. Depending on the chosen perspective, there are different measures of capital stock such as gross capital stock, net capital stock, and productive stock, alongside with the relevant measures of economic flows such as investment, depreciation, and capital services. The central economic relationship between these two perspectives is the so-called net present value condition according to which in a functioning market the stock value of an asset is equal to the discounted stream of future benefits (capital services) which the asset is expected to yield. For transport infrastructure, however, there are considerable difficulties in estimating future benefits that can be derived from an asset. This is the reason why alternative approaches, in particular the indirect valuation by using the perpetual inventory method (PIM), are applied. It should also be noted that the concept of capital services has been increasingly gained attention of researchers and has been suggested as an add-on in the 2008 version of SNA but has not yet formed a compulsory part of national accounts. For transport infrastructure, it is particularly difficult to apply, and given that it is a non-compulsory element of SNA, it will not be discussed further in this encyclopedia.

Capital stock accounting in company balance sheets is common practice for all private and also publicly owned companies; relevant examples are private motorway companies and rail companies. Apart from this, there are two approaches to determine the

value of capital stocks. These are the direct method, sometimes also referred to as synthetic method, and the indirect method, also referred to as cumulative or PIM. The focus in this encyclopedia will be on the PIM, which is the most common tool in the SNA of most OECD countries. Since the direct method is used as basis for deriving motorway tolls in some countries, and due to its potential role for compiling initial capital values as input for the indirect method, this encyclopedia gives a brief summary on this method. Entrepreneurial roles of calculating capital values of private and/or public companies will not be covered here, they can be found in the relevant literature in this field. It should be noted that these values are not comparable with those derived with the other two methods due to different evaluation principles, depreciation periods, etc.

Indirect Method by Modeling Approaches (Perpetual Inventory Method)

Basic Idea

The PIM is based on the idea that stocks are composed of cumulated flows of investments minus retired assets and efficiency losses of assets. This idea can be used to calculate both a gross capital stock (G_t) and a net capital stock (N_t). Starting with existing information on the gross capital stock of year t (G_t), the capital stock of the subsequent year $t + 1$ (G_{t+1}) can be calculated by adding the flow of investments ($I_{t,t+1}$, also referred to as gross fixed capital formation [GFCF]) and by deducting the retirement of assets ($A_{t,t+1}$).

$$G_{t+1} = G_t + I_{t,t+1} - A_{t,t+1} \quad (1)$$

The net capital stock (N_{t+1}) can be obtained in a similar approach, here by taking into account depreciation ($D_{t,t+1}$) of those assets which have survived from past investments.

$$N_{t+1} = N_t + I_{t,t+1} - D_{t,t+1} \quad (2)$$

The PIM requires long time series on annual investment expenditures for homogeneous groups of assets, information on service lives, and initial values on the capital stock as starting values for the PIM. The time series of investment expenditures should be sufficiently disaggregated into technically homogeneous capital goods to enable an adequate assignment of life expectancies. Depending on the asset's type and the assumed service life, these time series have to reach very long back into the past. Furthermore, an initial value for the capital stock is required except the case that the available investment time series exceeds the life expectancy of assets. Apart from the long investment time series itself, the calculation of capital stocks with the PIM requires a long time series of deflators to convert all investment vintages at the price level of a chosen reference period.

Gross Capital Stock and Retirement Distributions

The gross capital stock contains the stock of all assets surviving from past investments reevaluated at prices of new capital goods of a reference period. It can be thought of as the value of assets before deducting consumption of fixed capital (CFC), for example, economic decay of assets is ignored and past investments are considered as if they were new. For calculating the gross capital stock, a retirement or mortality profile of assets has to be assumed which models the retirement process of an asset cohort over time. The retirement function is a probability function with the underlying assumption that the life expectancies of assets within an investment vintage are dispersed around the mean value. Retirement is defined as the removal (discard) of an asset from the capital stock because it is abandoned, dismantled, sold for scrap, or exported. It should be noted that retirements are to be distinguished from disposals; this latter category also includes asset sales as secondhand goods for continued use in the production process. This latter category is of lesser importance for transport infrastructure assets, even though examples for second use of capital goods do exist (e.g., equipment, rail tracks from heavy track classes which are used at lines with lower track weight classes). The inverse of the retirement function is the survival function that describes the share of assets, which are still in use. An important assumption in capital measurement through the PIM is that assets are properly maintained and can be used until they reach their defined life expectancy. Retirements due to unforeseen events such as natural disasters are not considered within the retirement function but are treated a separate category.

The key parameter of the retirement profile is the average service life of an asset or asset group, and retirement functions can be truncated to fix a maximum service life. In practice, a range of functional forms for the retirement patterns is used (see [Table 1](#) which summarizes retirement functions, average service life assumptions, and depreciation patterns in OECD countries, and [Fig. 1](#)). Most of them are bell-shaped functions where retirements start gradually after the year of installation, build up a peak around the average service life, and decline gradually during the years after the average service life. Bell-shaped retirement patterns include the normal/lognormal, Gamma, Winfrey, and Weibull distributions.

Normal Distribution

The use of the normal distribution for retirement patterns assumes that asset retirements are symmetric with 95% of the probabilities to retire lying within two standard deviations around the mean service life. It is for example used in Hungary, in Malta (for non-dwellings), and in the United Kingdom; truncated normal distributions are applied in Israel and Italy.

Table 1 Average service life, retirement functions, and depreciation patterns for roads in official capital stock calculations of OECD countries

	<i>Service life</i>	<i>Retirement pattern</i>	<i>Depreciation pattern</i>
Australia	33	S3-Winfrey	Hyperbolic age-efficiency profiles

Lognormal Distribution

In the lognormal distribution, the logarithms follow a normal distribution with the mean μ and the standard deviation σ . It is a right-skewed distribution, for example, the probability of assets to retire is zero in the first year after installation and is concentrated in later years of an asset's life whereby the right-hand tail of the distribution has arbitrarily to be set at zero. The frequency distribution—with T as the age of assets—is:

$$F_T = \frac{1}{T\sigma\sqrt{2\pi}} e^{-(\ln T - \mu)^2 / 2\sigma^2} \quad (3)$$

μ and σ are calculated as $\mu = \ln(m) - 0.5\sigma^2$ and $\sigma = \sqrt{\ln(1 + (m/s)^{-2})}$ with m and s being the mean and the standard deviation of the underlying normal distribution. With m representing the average service life of an asset, commonly used parameter values for s in capital stock estimation in the European Union (e.g., in Belgium, the Czech republic, France, Lithuania, and Cyprus) are between $m/2$ and $m/4$. Empirical support for these values comes from discard surveys performed by the statistical office in France.

Winfrey Distributions

The group of Winfrey curves covers 18 typical empirical distributions (Winfrey, 1935). They are named after Robley Winfrey, a research engineer at the IOWA Engineering Experimentation Station, who collected information on installation and retirement dates of 176 groups of industrial assets, out of them also for railway assets and for road pavements. The Winfrey curves are denoted by L, S, and R for left modal, symmetrical, and right modal, and by the numbers 0–6 for flatter to more peaky curves. The most commonly used Winfrey curves belong to the group of symmetric S curves which is defined as:

$$F_T = F_0 \left(1 - \frac{T^2}{a^2} \right)^m \quad (4)$$

F_T is the marginal probability of an asset to retire at age T where the age T is expressed as the share of the average service life (in Winfrey's work expressed in deciles). This implies that T varies from zero to infinity and F_T takes the largest value at the average

Normal and lognormal
Blue = normal, green = lognormal

Weibull
Lambda = $b_1/0.0164$, alpha: green = 2.6, blue = 1.5, orange = 1.0

Gamma
Lambda = 9, alpha = 9

Third-degree polynomial
A0 = 0.00027, A1 = -0.00011 A2 = 1.18e-05
A3 = -9.87e-08

Figure 1 Different retirement functions used by OECD countries in capital stock estimation—density functions for service lives. *Source: Own presentation based on parameter values used by several OECD countries.*

service life. The most widely used Winfrey curves are the symmetrical S2 and S3 functions with the parameter values $F_0 = 11.911$, $a = 10$, and $m = 3.7$ for S2, and with $F_0 = 15.61$, $a = 10$, and $m = 6.902$ for S3. Winfrey-based retirement patterns are used for example in Sweden, Denmark, Australia, Korea, and Chile.

Weibull Distributions

The Weibull function named after the Swedish mathematician Waloddi Weibull (Weibull, 1951) is widely applied in engineering disciplines to study failure times of materials, and has also been used in modeling mortality in natural populations. The flexibility of the functional form allows accommodating similar shapes as the Winfrey curves. The Weibull frequency function, again with T as the age of the asset, is given as:

$$F_T = \alpha \lambda (\lambda T)^{\alpha-1} e^{-(\lambda T)^\alpha} \quad (5)$$

where $\alpha > 0$ is the shape parameter and $\lambda > 0$ is the scale parameter of the distribution.

Weibull retirement functions are used by the statistical offices in the Netherlands and Finland for capital stock estimations. The parameter values for the Weibull retirement functions used in the Netherlands are based on a discard survey conducted by Statistics Netherlands which yielded for buildings λ -values in a range from 0.021 to 0.05 and α -values between 0.97 and 2.21. For other tangible fixed assets similar ranges of 0.028–0.108 for λ and of 0.98–2.63 for α were obtained (Meinen et al., 1998; Rooijen-Horsten et al., 2008).

Gamma Distribution

The Gamma distribution is used by the German Statistical Bureau for modeling asset retirements. In absence of a discard survey for industrial sectors, it is empirically based on observed patterns of car registration and retirement. The Gamma retirement distribution is:

$$F_T = a p \Gamma(p)^{-1} T^{p-1} e^{-aT} \quad (6)$$

The parameters a and p which determine the shape of the curve are set equal to 9 for most capital goods in Germany (Schmalwasser and Schidlowski, 2006).

Polynomial Retirement Function

The capital stock estimation for German transport infrastructure, compiled annually by the German Institute for Economic Research (DIW Berlin) in addition to the official SNA-based capital stock calculations of the German Statistical Bureau, uses a third-degree polynomial retirement function. Under the assumption that retirements start at year t_s with $t_s > t_0$, the parameters of the polynomial

$$F_T = \beta_0 + \beta_1 T + \beta_2 T^2 + \beta_3 T^3 \quad (7)$$

can be obtained from the lower and upper limits of the service life intervals s and L , with a mean service life of $m = s + 0.6(L-s)$. This right-skewed form has found to reflect the specific long life expectancy of assets and the fact that mostly discards of such assets are concentrated at the right-hand side of the tail (see Link et al. (1999) for an application to roads in different EU countries and Link et al. (2019) for a more recent discussion on the specific properties of transport infrastructure capital).

Discussion

It should be noted that discard surveys as basis for statistical estimation of retirement functions and average service lives are almost impossible to conduct for transport infrastructure. Annual discards or sales of pavements, rail tracks, runways, etc., are in practice not relevant. Official calculations of statistical offices therefore transfer service lives and retirement functions from other sectors to the transport sector.

Service Lives

Service life of assets—one of the most crucial parameters of the PIM—is defined as the length of time that an asset remains in the capital stock. It includes both the time in the capital stock of the purchaser and in the stocks of other producers who bought the asset as secondhand good. Asset life in capital stock estimation models means the economic, not the physical or engineering notion of service life, for example, assets could physically still be in use but are discarded due to economic obsolescence. Most retirement distributions require defining the average service life, to be distinguished from the maximum service life of an asset within a cohort of assets. Sources to obtain service life information include tax authorities (tax lives), company accounts, expert estimates, and statistical surveys. For transport infrastructure, tax lives play a minor role, but can give indications on service life, in particular for equipment goods in ports, stations, or airports. Although the PIM requires the economic lifetime of assets, engineering-based information on service life is a relevant starting point for transport infrastructure, in particular regarding the relationship between traffic volume and infrastructure damage at roads and rail tracks. Table 1 gives an overview on service life assumptions for roads, together with the retirement pattern, for selected OECD countries.

Transport infrastructure has characteristics that add complexity to the definition or estimation of service lives compared to other sectors. In particular, the long lifetimes of 50 years and above imply that complete observations of service lives are often lacking, and the mortality function has to be chosen without complete observations of an empirical distribution. The cause–impact relationship between service life and various impact factors such as construction standards and construction quality, dimension (e.g., thickness of road layers, weight class of rail tracks), climate, topography, traffic volume, and traffic composition is complex. To this adds the problem that conventions on a minimum quality of service have to be defined which impact on the service life of infrastructure that can differ from a pure physical life expectancy.

Net Capital Stock and Depreciation

The net capital stock, also referred to as wealth stock, is the stock of assets that have survived from past investments minus the annual depreciations. Estimates of net capital stocks have to be considered within a broader set of capital measures that reflect the dual role of capital as storage of wealth and as the source of capital services in the production of goods and services.

For calculating net capital stocks, a depreciation function has to be derived which reflects the decrease of the value of assets during their service life. In the SNA, depreciation is defined as the decline or loss of the current value of the stock of fixed assets due to physical deterioration, normal obsolescence, or normal accidental damage during the accounting period. The decline or loss of asset value is the reason why depreciation is also referred to as CFC; in national accounting of the United States the term capital consumption is used.

Since, for transport infrastructure, information on depreciation cannot be derived from observed market transactions, assumptions are necessary. In principle, there are two approaches to define and quantify a depreciation profile. For a single homogeneous asset, the age–price profile shows how the asset price declines as a consequence of ageing, reflecting CFC due to physical deterioration (wear and tear) and normal obsolescence. In practice, this is the most common way and statistical offices often assume a linear depreciation function with constant absolute values of depreciation over time. The second approach is to consider the age–efficiency profile of the homogeneous asset that reflects the change of productive capacity over time. It provides the link to measuring capital services, for example, the asset's contribution to production. Both profiles are related and can be derived from each other. The most common depreciation patterns are linear (straight line) and geometric (see Fraumeni (1997) for an outline of both approaches).

While for a linear depreciation pattern, an asset with a service life of T loses each period a constant amount $D = 1/T$ until the asset value is zero (e.g., constant absolute values in each period), in a geometric depreciation pattern an asset loses its value at a constant rate δ each year. Geometric depreciation profiles are also called to be “convex to the origin” since the amount of absolute depreciation is highest at the beginning and declines over time. Empirical evidence that geometric profiles are appropriate for many types of assets is given in [Hulten and Wykoff \(1981\)](#) and [Koumanakos and Hwang \(1988\)](#). An overview on depreciation studies can be found in [Jorgenson \(1996\)](#). It is recommended to derive the parameters for geometric models of depreciation from econometric studies based on empirical information on prices for used assets. For transport infrastructure, but also for various other types of capital goods this is often hampered by the lack of such empirical information. A simple method for obtaining a geometric depreciation profile in such cases is the double-declining balance method where the rate of decline is given as $\delta_i = 2/\bar{T}_i$ with $\bar{T}_i$ as the average service life of asset type i . It should be noted that in many empirical studies values different from 2 are found, with no clear results supporting values below or above 2.

Most advanced capital stock estimation schemes consider cohorts of assets instead of single homogeneous assets and assume retirement distributions for these cohorts (as discussed earlier). The combination of age-efficiency profiles and retirement distributions often yield “convex to origin” depreciation patterns which are alike geometric depreciation. For example, this is the case for a bell-shaped retirement distribution for a cohort of asset and a linear depreciation for a homogeneous asset. Since geometric depreciation is supported by empirical studies, the OECD recommends the use of geometric depreciation profiles. The ESA, which is the current accounting standard for European countries, recommends linear depreciation as the standard tool, but recognizes the advantages of geometric depreciation and recommends it in cases where necessary. In practice this means that both approaches are possible, but most common seems to be the linear depreciation profile. As [Table 1](#) shows, only few countries use linear depreciation patterns without retirement functions, while for many countries linear depreciation patterns in combination with mortality distributions yield quasi-geometric depreciation profiles. Apart from linear depreciation, geometric depreciation is the second most common form. Finally, there are also few countries using other depreciation patterns. Australia and Korea apply hyperbolic age-efficiency profiles which in combination with Winfrey S3 retirement functions tend to resemble geometric depreciation patterns.

Gross Fixed Capital Formation (GFCF)

Apart from service lives, retirement distributions, and depreciation profiles, investment time series is one of the key ingredients to the PIM. In the SNA, investments are defined to contain all acquisitions of new as well as secondhand capital goods minus disposals, plus major improvements of assets (in particular of buildings, dwellings, etc.) and transfer costs (e.g., fees paid to surveyors, engineers, architects, as well as taxes within the transfer of ownership). This category is also termed as GFCF. An important link between GFCF and running expenditure is the relationship between ongoing maintenance expenditure and renewals or replacement investments. The first category does not enter the calculations of capital values due to its service life of less than 1 year, but it nevertheless impacts on the capital values in so far as inadequate maintenance reduces the expected service life of the asset. As outlined earlier, the PIM is based on the assumption of adequate maintenance of all capital goods and violations of this assumption places considerable challenges to the adequate measurement of capital stocks (e.g., problems in correcting service life figures due to under-maintenance of assets). In practice, the line between ongoing maintenance spending and renewal investments is fluent and empirically not easy to draw. The relevant criterion is the durability of the expenditure: all expenses whose service lives exceed the accounting period (usually 1 year) are treated as investments.

Investment data should be broken down to technically homogeneous types of assets in order to enable assignment of service lives and retirement distributions. For example, the German capital stock calculations for transport infrastructure distinguish four types of capital goods for roads and six types for rail. Furthermore, the time series need to be deflated by price indices for the capital goods in question. This again is an empirical matter since ideally different construction and equipment price indices are required (e.g., for roads differentiated by types of pavement constructions and by bridges and tunnels, in rail differentiated by tracks, bridges and tunnels, station buildings, signaling, etc.).

Estimating an Initial Value of the Capital Stock—The Direct (Synthetic) Method

Transport infrastructure is characterized by long-living capital goods which may in many cases not only exceed 50 or 60 years but even 100 years (e.g., structures). As a consequence, long time series of investments as ingredient to the PIM may not be available. Apart from constructing the necessary time series (e.g., by econometric analysis of the relationship between GDP and investment), it is a common practice to produce a benchmark or initial value of the capital stock. This is, as far as possible, based on statistical surveys, census, or administrative property records. The basic principle of the direct method is to produce an inventory of assets in physical units (e.g., for roads in terms of indicators such as length, width, number of lanes, tunnels, bridges, etc.) and to value these units by unit costs. The direct method requires a huge expense of time, and small errors in unit costs can contribute to considerable deviations of the estimated value from the true (unknown) value. The importance of such deviations, however, will diminish over time as the base (initial) period is left behind.

The direct method is not only used for deriving starting values for capital stock estimation with the PIM. This method is also one of the feasible methods defined in the EU directive of road toll calculations ([European Commission, 2011](#)). Germany has been using

Table 2 Investment and capital stock of transport infrastructure in Germany 2017 (€ million, at prices of 2010)

	<i>Investment spending^a</i>	<i>Capital stock</i>	
		<i>Gross^{a,b}</i>	<i>Net^{a,b}</i>

this method as basis for deriving depreciation and interest within the toll calculations for heavy goods vehicles on motorways since 2005 (Alfen et al., 2018).

An Example of Capital Stock Estimates for Transport Infrastructure

Table 2 gives an example of annually compiled, fully-fledged capital stock estimation for transport infrastructure for Germany (BMVI and DIW, 2018). Methodologically, it is based on the PIM compatible to the official capital stock estimations of the German Statistical Bureau for all sectors, but uses instead of the Gamma function for retirements a right-skewed third-degree polynomial distribution. Depreciation is calculated with a linear function so that in combination with the retirement function a quasi-geometric depreciation profile is obtained. The level of disaggregation varies between consideration of two groups of assets up to six groups for rail and rail-based public transport. Figures for the overall transport sectors, for example, including vehicles and transport companies, are given in the last row. Transport infrastructure makes up more than half of investments and—due to the long service lives—around 85% of capital stock. The most important mode in terms of capital value is the road network followed by rail.

Increasing Importance of Transport Carbon Emissions Worldwide

Transport emits CO₂, the most important greenhouse gas (GHG) and if global warming crosses the critical threshold of 2 degrees Celsius that will lead to even catastrophic consequences for our planet (see IPCC report of 2004). Transport activity and transport-related carbon emissions have increased significantly in the past decades. The transport sector has been responsible for 23% of total energy-related CO₂ emissions in 2010. Transport emissions have increased by the factor of about 2.5 during the period 1970–2010 and are still growing. According to the Fifth IPCC report (IPCC, 2014), transportation by road has contributed 72.6% of the total direct transport GHG emissions in 2010. International and coastal shipping and domestic and international aviation have contributed, respectively, 9.26% and 10.62% of the total direct GHG emissions of transport (Fig. 1).

ITF Transport Outlook 2019 (OECD, 2019) is an overview of recent trends and near-term prospects for the transport sector at a global level, as well as long-term projections for transport demand to 2050. The analysis covers freight (maritime, air, and surface) and passenger transport (car, rail, and air), as well as related CO₂ emissions, under different policy scenarios. ITF Transport Outlook 2019 states with some confidence that, globally, demand for mobility will continue to grow over the next 3 decades. Passenger transport will increase nearly threefold between 2015 and 2050, from 44 trillion to 122 trillion passenger-kilometers. According to the ITF scenario, China and India will generate a third of passenger travel by 2050, compared with a quarter in 2015. Aviation passenger-kilometers in India and China alone are expected to increase almost fourfold by 2050, to 21,583 billion from an estimated 5,506 billion in 2015.

In accordance with ITF model calculations, global freight demand will triple between 2015 and 2050 based on the current demand pathway. At 4.5%, airfreight is expected to have the highest compound annual growth rate of all modes through 2050, although representing a small share of total freight tons-kilometers. More than three quarters of all freight will continue to be carried by ships in 2050, more or less unchanged from 2015.

The main challenges and barriers preventing the reduction of transport GHG emissions are incomplete international agreements related to regulation of transport as well as the current high costs of clean transport technologies. The importance of emissions associated for example with international freight transportation of industrial goods is largely overlooked in the existing climate agreements.

It is possible to bring down the (relative) costs of clean transport technologies by using the combination of taxes and subsidies on specific fuels and types of transport technology with long-term investments into transport-related R&D activities. However, this (see IPCC report of 2015) will not be sufficient for the needed drastic reduction of the amount of transport-related GHG emissions. Economic policy instruments should be supplemented by command and control actions such as closing the coal mines and coal- or gas-based electricity plants (Fig. 2).

According to the projections of ITF Transport Outlook 2019 (OECD, 2019), transport CO₂ emissions will globally remain a major challenge. The extrapolation of current policy ambitions into the future shows that these will fail to mitigate increases in transport CO₂ emissions due to the strong growth in transport demand over the coming years (especially related to the international freight transport). In an ITF baseline scenario where both current and announced mitigation policies are implemented, worldwide transport CO₂ emissions are projected to grow by 60% by 2050. The growth in transport emissions is driven mainly by increased demand for freight and nonurban passenger transport, both of which are projected to grow 225% by 2050. Emissions from urban passenger transport, on the other hand, are projected to fall in the baseline scenario by 19%, reflecting existing strong focus of current policies on urban transport.

Both freight and passenger transportation by road and air contribute significantly to the generation of GH emissions. The share of road transport is the largest for both passenger and freight transport with the use of gasoline and diesel as two main types of fuels. The

Figure 1 Development of the direct GHG emissions of the global transport sector. Source: Fifth IPCC report.

Figure 2 Share of transport as a part of total direct GH emissions in EU28. Source: Eurostat.

use of elective vehicles still remains marginal in most of the countries and globally. Rail being less emitting mode of transport is used marginally both for passenger and for freight transportation (Fig. 3).

Main Economic and Behavioral Drivers of Road and Air Transport

Transportation is an integral part of our daily lives and is a prerequisite for economic growth and prosperity. Various studies have demonstrated that good transport infrastructure and high personal accessibility lead to the economic growth and households' income by improving the access to labor market and allowing for better matching between available vacancies and persons searching for new jobs (Santos et al., 2010). Significant decrease in international freight transport costs has contributed to the ongoing process

Figure 4 Regional distribution of transport GHG emissions. Source: Fifth IPCC report.

instruments because they allow reduction in emissions in the most costs effective way for both consumers and producers. Price instruments also give producers and consumers the freedom to determine themselves how they would like to reduce their emissions; this could be via investing in more fuel-efficient vehicles, traveling less, or adapting their driving style. Gasoline and diesel are heavily taxed both in EU and in Japan where the taxes are often more than 200% of the fuel price. Fuel taxes function both as a GHG emissions tax and the tax on the use of transport infrastructure, and the tax revenues from fuel taxes are often earmarked for transport infrastructure investments.

With regard to road transport, the most widely used instrument to reduce emissions is the combination of vehicle registration taxes that are related both to car's environmental performance and to its characteristics such as engine power and weight with fuel taxes. The first type of taxation is intended to discourage the purchase of more polluting cars and the second one is intended to discourage intensive driving with the car.

It is important to realize that about 50% of all new passage car sales in EU are company cars, which are often used by employees for both business and personal travel. Companies pay for both cars and fuel used by their employees and can subtract those costs from their taxable revenues. Besides this, it is often that company cars are subject to preferential taxation that results in the loss of 54 billion of Euros per year in EU according to several studies (Gossling and Cohen, 2014). Such tax arrangements provide a clear incentive for employees to by larger and heavier cars that use more fuel as well as to drive them more. It is also true that most of the super mobile individuals that drive a lot have such company cars and hence no actual incentive to change their travel behavior.

In the recent years, various countries have introduced subsidies on purchase of electric cars in the hope to reach reduction of road transport emissions. Due to the relatively high prices of electric vehicles most of these cars are currently also company cars. It is hoped both by policy-makers and by the researchers that gradual reduction in the prices of electric vehicles will make them attractive for various income groups and that current electric company cars will soon become available at the secondhand car market for more reasonable prices.

Overall price-based measures related to road and air transport do not consider individual contribution to transport emissions and also do not take into account income inequalities that affect mobility behavior that could be of importance to efficient reduction of transport-related emissions.

The environmental policy instrument that is explicitly designed to regulate GHG emissions is a tradable emissions scheme. The main advantage of this policy instrument is that the costs of emissions reduction costs between the polluters are distributed in the most efficient way and hence the GHG emissions reduction is achieved at the lowest costs. From the point of view of the environmental economic theory the introduction of ETS system should result in reduction of emissions in the most efficient and cheap way because the companies who can easily and cheaply reduce their emissions will do that and sell their remaining emissions permits to the companies that cannot reduce their emissions that are easy and cheap.

European Trade System (EU ETS) is one of the examples of the successful implementation of a tradable emissions scheme. The main idea behind EU ETS is to have a fixed amount of emissions permits that are distributed to various companies according to their historical emissions and to allow them to trade these emissions permits between each other such that the price of one permit is determined by the interplay between demand and supply of emissions permits. The fixed number of emissions permits should decrease over time that would result in the decrease of overall emissions and an increase in the price of emissions permits.

Despite the solid theoretical foundations of EU ETS, its efficiency has been undermined by too low prices of the emissions permits that did not provide airlines with sufficient incentives to invest in reducing their emissions or to increase their prices.

CO₂ emissions from aviation have been included in the EU ETS since 2012. Under the EU ETS, all airlines operating in Europe, European and non-European alike, are required to monitor, report, and verify their emissions, and to surrender allowances against those emissions. They receive tradable allowances covering a certain level of emissions from their flights per year. It is well possible to also include road transport into the road transport by requiring the permits upstream at the level of fuel distributors. EU ETS system for road transport could potentially replace the existing fuel taxes if the price of carbon is set up on the correct level.

In addition to market-based measures like the ETS and taxes, regulatory measures—such as efficiency standards, alternative fuels, and modal shift to rail and public transport—also contribute to reducing road and aviation emissions.

The use of efficiency standards next to fuel taxes is justified by the energy efficiency gap which means that consumers and producers might be to some degree myopic and they may underestimate the energy savings associated with more fuel efficient cars. The degree of the effectiveness of fuel standards depends on the degree of the myopic behavior among the consumers and producers. An alternative to fuel standards is the co-called “feebates” that represent a combination of fees on the producers of vehicles that fall below the efficiency standard with subsidies to the producers whose vehicles perform better than the efficiency standard. Feebates programs are usually designed to be revenue neutral meaning that the collected fees are equal to the paid subsidies.

Another reason to use efficiency standards is the process of technology diffusion. Introduction of efficiency standard in one large country or a group of countries will result in changes in the production technology of the vehicles and the enhanced more fuel efficient vehicles will be sold all over the world leading to reduction in GHG emissions in other parts of the world as well (in contrast to the implementation of fuel taxes).

In case of passenger road and air transport stimulating the shift from road to public transport and from air to rail transport is often seen as one of the policy options to reduce GHG emissions. High occupancy rates of public transport and rail in some countries as well as the use of alternative clean energy types make them attractive alternatives for road and short-distance air if one wants to reduce GHG emissions. The modal switch is quite a costly public policy that requires large investments into public transport infrastructure and these investments in most of the cases cannot be fully recovered via the prices of tickets. Moreover, building new railways infrastructure is in itself associated with high GHG emissions. Ticket costs of public transport and rail need to be kept low in order to promote switch from road and air transport.

Indirect Effects of Policies: Carbon Leakage and Rebound Effect

Reduction of the transport-related GHG emissions in any particular country has only small impact on the overall level of GHG emissions worldwide. The reduction of GHG emissions as a result of reduction of the fossil fuels by one particular country may be partially or even completely offset by the so-called “carbon leakages” and “rebound effects.” These two mechanisms are related to economic behavior of producers and consumers and the global nature of our economies.

Carbon leakage comes in two important types: spatial leakage and intertemporal leakage (Eliasson and Proost, 2015). Spatial leakage occurs when one country puts in place the regulation of GHG emissions and the other countries do not do that. Introduction of more stringent GHG emissions regulation may result in relocation of polluting activities to the countries with less stringent regulation which lead to less reduction in global GHG emissions as without relocation of economic activities or even their overall increase. Relocation of activities might not be as large problem for transportation sector as it is for the industrial sector but a sufficient decrease in the demand for fossil fuels may result in a decrease in their global prices and increase consumption of fossil fuels in the rest of the world. According to the empirical studies, spatial leakage can offset initial reduction of GHG emissions by 10%–30%.

Intertemporal leakage occurs when all countries in the world put in place more stringent regulation of GHG emissions. In case when the price of oil stays in the future period higher than the costs of oil extraction, the companies that produce oil will

be interested in selling their full oil reserves. This means that the introduction of more stringent regulation will result in a temporal shift in the consumption of fossil fuels without changing the total amount of their consumption and associated emissions. However, fast reduction of GHG emissions may prevent further speedup of the climate change process. Only in a particular case when there will be a new technology that is alternative to fossil fuels and that is also cheaper than the costs of oil extraction will the world have an economic incentive to switch from fossil fuels to the clean alternative. The crucial determinant of the consumption of fossil fuels and the associated GHG emissions over time is the relationship between the costs of alternative clean technology and the costs of the oil extraction. Worldwide implementation of alternative clean technology will become economically profitable only when its costs are lower than the costs of extracting oil and not when there are lower than the price of oil.

Policy and technological measures that improve fuel efficiency of road and air transport are typically offset by rebound effects that could be direct, indirect, and economy-wide. These rebound effects differ between various household groups with larger rebound effects being associated with poorer households. Rebound effects are related to the behavior of households when choosing their consumption patterns when they have more income to spend due to fuel savings while driving their car or cheaper airplane tickets.

Direct rebound effect corresponds to an observation that when driving more fuel efficient car persons will start driving more as compared to their use of less fuel efficient car because the use of car per kilometer driven is now cheaper. Indirect rebound effect describes another way in which extra money due to fuel savings can be spend by the households. Instead of driving a bit more they could choose to spend their extra money on other types of consumption such as for example food or clothes. These extra consumption in itself is related to energy use and emissions that have been used during its production process lead to an offset of an initial fuel and GHG emissions savings associated with improved fuel efficiency of vehicles. Economy-wide rebound effects describe the impacts along the whole production chain of the additional goods and services that the households have purchased with the money saved due to improved fuel efficiency and capture the notion of the economic multiplier effect. Extra production of goods and services for the purchase by households generates extra income that is spend in the economy and this extra income itself results in even larger increase in production of various goods and services and hence even higher offset of initial fuel and GHG emissions savings. The magnitude of the rebound effect ranges from 10% to 30% of the initial fuel savings.

Conclusions and Policy Implications

Taxes and changes on purchase of vehicles and fuel use are used extensively throughout the world. Most countries levy a registration tax on new vehicles and annual vehicle excise duties. In the recent years, several countries have also introduced subsidies to fuel efficient and electric vehicles, feebates, and scrappage incentives. Most countries of the world also have fuel taxes that vary substantially between them. Mexico and the United States have very low fuel taxes as compared to EU and Japan. In many of the EU countries fuel taxes represent a significant part of the governmental tax revenues (between 4% and 6%). If the transport sector would not use carbon fuels anymore, the governments would need to introduce some additional alternative taxes in order to compensate for the loss of revenues from fuel taxes.

It is important to realize that any assessment of costs and benefits of policies for reduction of road and air GHG emissions should take into account that this emissions reduction will be at least partly offset by spatial and temporal leakages and rebound effects. One should also notice that the worldwide oil reserves will be used up to the point when the costs of clean alternative are lower than the costs of oil extraction. However, reducing current demand of road and air transport for fossil fuels might be effective in postponing oil extraction and the associated GHG emissions to the point when new clean technology will become significantly cheaper.

Replacing fossil-fuel-driven cars with electric ones will only lead to reductions of GHG emissions when the used electricity is produced using renewable energy sources. If the electricity is produced using coal and gas, the switch to electric cars may result in increase of overall GHG emissions.

The rebound effect is important for determining the level of efficient policy instruments such as standards and taxes. The policy-makers should pay sufficient attention to the heterogeneity of the rebound effect. Research shows that household characteristics such as income and age as well as driving intensity lead to significant heterogeneity in the rebound effect and make uniform policy ineffective in diminishing it.

Governments can currently choose from a pallet of different policy instruments aimed at reducing GHG emissions of road and air transport in order to address the problem of climate change. The actual implementation depends on the will and commitments of the governments.

Toll Highways: A “Natural Monopoly” with a Nonnatural Financing System

Efficiency, Budget Constraints and Distributive Issues

Natural monopolies, differently from “pure” public goods, have no rivalry in consumption but are “excludible”, that is, the users have to pay a tariff “Pure” public goods are neither rival (no one is damaged by an additional user), nor excludible (no one can impede its use). The lighthouse is the classic example of a pure public good. Natural monopolies lack the excludability condition: one has to pay for using them). But in case of roads, to impose a tariff (named “toll”) is a pure political choice: actually, the majority of roads are without tolls, that is, are “pure” public goods. (If a road is congested, actually rivalry of consumption ensues, in the sense that each added user reduces the quality of the service provided by that road, but we will see this issue in the final point).

Let’s see first the economic rationale of imposing a toll. In theory, the maximum efficiency in the use of infrastructure is reached when the users pay for the costs they generate to the infrastructure itself, that is, wear and tear (this rationale of tolling is known as “Marginal Cost Pricing”, MCP, and obviously implies that the investment costs are paid by the State, that is, the taxpayers, and also this issue presents some problem, as we will see).

Why not making the users pay also for the investment cost? Because some users, if they have to pay also for this cost, will non travel, even if their utility in travelling is actually larger than the cost that they generate travelling, that is only, as said, wear and tear. If their benefits are higher than the costs they generate, it is efficient that they travel.

The environment and safety cost are also to be paid for (see in particular the well-known principle “polluters pay”), but not for the use of a specific infrastructure: it is simpler and more sensible to charge directly these costs where they originate, that is, with the taxation of fuels and with the insurance system.

This, seen from the basic social welfare theory (including the environmental aspects). But in general road tolls include totally or partially the investment costs, on top of the wear and tear ones. What is the motivation of this apparently inefficient policy (known as the “Average Cost Pricing”, ACP, because it tends to cover the entire cost of the infrastructure)?

In theory, it depends on the scarcity of public money. This scarcity in turn can be translated in a social opportunity cost for this resource (MOCPE, Marginal Opportunity Cost of Public Funds). A country with a balanced budget is evidently in a different position of a one heavily in debt. Therefore, a trade-off is set between the efficiency of the use of the infrastructure and the scarcity of public funds. (The exact value of this trade-off in turn depends on the elasticity of traffic demand to tolls and the magnitude of the MOCPE. Formally, it is a problem of constrained optimization. Anyhow, the higher the elasticity and the lower the MOCPE, the lower is the “optimum” toll level).

A distributive issue may also come in play: if only the users pay for an infrastructure, the taxpayers that will never or seldom use it, will not. Those who benefit will pay for their benefits.

But here a severe political problem arises, as we will see later: why quite often in Europe the users of some type infrastructure are charged at ACP (i.e., pay a lot), and others, using different transport modes, are charged at MCP (i.e., pay little)? The larger difference is between toll road and rail users, even those of HST. Political consensus (and not the environment) is often at play, but we cannot extend here the issue in more details.

Regulatory Principles: Simulating Competition Pressure, Rewards and Constraints in Order to Improve Efficiency and Protect the Users, Lacking the Real Incentives of the Market

As any monopoly, also this one requires public, independent regulation. The market incentives and pressure take care, for private goods, of incentivizing efficiency (inefficient firms will show either higher costs or inferior quality of production, and loose out against competitors), and protect consumers from excessive prices (competition tends to minimize prices). A basic question emerges here: if the toll roads are kept public as the nontoll ones are, the State will take care itself both of efficiency and of fair tolls. And here enters the issue of “capture” of the political decision makers. Efficiency tends to be in conflict with consensus, that is an explicit and legitimate political objective: no favors can be made to employees nor to suppliers, quite the contrary. Extracting rents from the users with excessive tolls is also a strong temptation, that furthermore becomes necessary if the management is inefficient. “Capture” is the synthetic term that describes a situation where the public interest succumbs to socially non acceptable goals (even plain corruption is encompassed by this term).

Therefore, it is a worldwide tendency to institute independent regulatory bodies (Ponti, 2011), endowed with technical capabilities, and with severe constraints on the behavior of the managers, that for example cannot work for many years after their appointment for former regulated companies. These bodies are in charge of periodically setting the tolls and tendering out the concessions when they expire. The controlling of the maintenance and construction activities, and the quality of the services provided by the concessionaires are generally delegated to the Ministry of Transport, since the needed technical capabilities are already there, due to the existence of a much wider network of nontoll roads.

All these issues are even more compelling since in general the toll roads are tendered out to private companies. This happens often under the assumption that private companies, especially under the pressure of competitive tendering, are more efficient than the State. This “assumption of efficiency” is frequently extended not only to the building and maintaining activities, but also to traffic managing, even if, as we will see, that this is a far less defensible assumption.

Furthermore, it is also assumed the concessions have to be very extended in time, in order for the concessionaires to have the possibility to recover, via the tolls, the investment costs, given the fact that in general these costs are included in the pricing regime (ACP).

This last assumption, as we will see, is also very questionable.

More on the Financing Issue: the Problem of “Asymmetry of Information”. The Basic “price-cap” Formula and its Foundations

So far, so good: the users have to pay, under independent public regulation, fair tolls, covering both efficient construction costs (partial or total), and efficient maintenance costs, related to the infrastructure that they are using. But the regulator, that is in charge of setting these fair tolls, ignores what are “efficient” costs, that can vary due to several different and specific causes. The concessionaire, at the contrary, knows them well (this fact is known as “information rent”). Furthermore, it has an objective, as every firm has, of maximizing its profit. And a reasonable profit has to be included in the “fair toll”, in order to induce any firm to take on whatsoever activity. It follows that the concessionaire, even if perfectly honest, has an implicit incentive to maximize its costs, being the “admitted” profit a fix percentage of these costs.

The solution for this problem is based on changing the incentive of the concessionaire. The more common strategy is to induce the firm to become efficient, setting the costs in advance after a negotiation: if it is able to save against these guaranteed revenues, it will increase its profit, and in a following round of toll setting, the regulator can have better information on the efficient costs, on which to base the level of the tolls.

The dominant practical instrument set for getting this result is slightly more complex, and it is known as the “Price cap” formula (Coco, 2008), that has to be set for a definite period constant in length (generally 5 years, and this length is known as “regulatory lag”), and then re-negotiated for each following period:

$$T + 1 = T(\text{CPI} - X + Q)$$

where T is the initial toll, based on the existing information on the annualized costs of the concessionaire including the admitted level of profit. $T + 1$ is the toll of the following year.

CPI is the Consumer Price Index (inflation has to be paid, since it is an “external” factor of cost increase). X is the annual (negotiated) increase of efficiency expected, and for this reason with a minus sign. Q is a (negotiated) quality-related factor (in toll roads, may be asphalt quality, lighting, toll-collection speed etc.).

The formula incentivates the concessionaire to become more efficient: if its costs decrease more than the negotiated X factor, its profit (that is the difference between its costs and the toll-related revenues) will increase in proportion.

In each period (“regulatory lag”) the regulator increases its information, via the negotiation itself, via some benchmark activity, and even directly observing the activities of the concessionaire during the period.

In the case that the concessionaire is so efficient to lower its cost more than is set for each period by the X factor, it will make extra-profits (a deserved prize for efficiency, as in a market context), but non forever: at the end of each regulatory lag the regulator will set

the toll level allowing for a fair level of profit, not more (This is known as the “claw back” principle, and is consistent with what happens in a market context).

The Traffic Risk: A Wrong Assumption in Risk Assignment

A basic principle of regulatory theory states that the risks left to the concessionaire have to be limited to the ones that it is able to control and manage, and therefore deserve a compensation in proportion of its results. Costs are for sure the more evident risk that it is correct to leave to it. But a firm operating in the market has to face also demand risks. It may change due to competition, the quality and the pricing strategy for its own products, the effectiveness of advertising etc. If a firm is successful, this component is at least as important as cost management. In the price-cap formula it is stated only the level of tolls, and therefore it is implicitly assumed that the higher the traffic, the higher the revenues (and vice-versa), and being the costs mainly constant with the traffic, so it goes for the total profits (or losses).

But this for toll roads has no economic sense: traffic is basically outside the control of the concessionaire. It depends mainly from the overall economic growth (GDP), demography and land use, and alternative infrastructure and transport services and prices.

And if a variable that is outside the control of an economic agent is left to it to be taken into account, it will correctly charge a high “risk price” related to the possible variations of the noncontrolled variable. This will result in a level of toll requested by the concessionaire to the regulator much higher than the efficient one, therefore generating an underutilization of the infrastructure.

It follows that the gains or the losses related to traffic variation have to be left outside the risk boundaries of the concessionaire. In reality often it is not so, due to several factors, mainly related to an historical picture of a rather constant and foreseeable traffic increase, but also to some form of “capture” of the regulator by the concessionaires.

Including in the toll a “risk price” rises its level, and the political decision makers may well have a “hidden agenda” favorable to high tolls, and if the regulator is not independent, may yield to political pressures. The above-mentioned “hidden agenda” is related to the tax revenues: the higher the profit of the concessionaire, the higher the income for the state, that for example in Europe has a level of taxation on profits in average well above the 30% threshold.

More Technical Issues: How Investments are Treated, the “Fair” Admitted Profit, the “Regulatory Asset Base” (RAB), Quality and Maintenance

Up to now, “costs” have been treated as a single concept, just mentioning the subdivision in investments and maintenance/operating costs. But in the case of infrastructure, they are basically different. The decision to build or even enlarge an infrastructure is basically a public one, and in case of roads this is made even more evident by the fact that the majority of roads is totally public, and without tolls. So what is the correct role of the actors involved, in this case? The public decision maker has to plan for a new road (hopefully based on some cost-benefit analysis) and decide if it deserves a partial public funding, and the concessionaire has to build it at minimum cost, repaying it with the corresponding tolls within a planned number of years. The possible problems here are two-faced: if the admitted profit is high, the concessionaire may “incentivate” the decision maker to build more than the necessary (a form of capture), or, in the worst case, delay the construction in order to get undue benefits from the tolls, if he is able to keep them unvaried notwithstanding the delay.

The above-mentioned admitted profit is not supposed to be arbitrary, of course.

In theory it has to be based on two components: the cost of capital (technically: the Weighted Average Capital Cost, WACC) plus an already mentioned risk premium. But in practice here there is wide space for “capture”, if the regulator is not independent, as we will show later in some example.

Another aspect concerns the scope of regulation, that is which activity of the concessionaire has to be regulated (here the technical term is Regulatory Asset Base, RAB): of course its core business, that is the road (construction, maintenance etc.). But there are important auxiliary activities that can be left to the market for their efficiency, mainly the resting areas and the connected gas stations. These activities can be auctioned periodically with an independent procedure.

Quality and maintenance are still a different issue: quality may enter in the price-cap formula, as we have seen, but its control, as for the far more crucial maintenance activities, are generally delegated, as said, to the Ministry of Transport, or to a similar technical body.

Issues Concerning the Risk of the Capture of the Regulator

Let's return on a basic question: why an independent regulator is considered in general necessary? The Ministry of Transport for sure can have all the technical resources needed to perform any required activity, both of regulation and control. The only justification is the widespread experience of “capture” of politically elected actors: they have a fully justified objective of pursuing political consensus, but this is exactly the contrary of what is needed for efficiency. Consensus is far better achieved by spending that by saving public money.

There are a set of issues that are related with the risk of capture (a risk that concerns to some extent also the independent regulator, but it is impossible here to elaborate more on this).

Let's start with the "correct" duration of the concession. The common wisdom is that its length has to permit to the concessionaire to fully amortize its investment, in order to be incentivated to build with solid technical standards, minimizing the overall maintenance costs. But there is a correspondent risk of capture linked with excessive "friendship" that may ensue, due to several years of collaboration with the technical staff of the regulator. Is it possible to define instead efficient contracts setting fair conditions of "succession", as the one resulting from a "new entrant" winning the tendering of the concession after a shorter period of time.

Related to this, is the basic issue of the assignment system. In theory, if it is made via a competitive tendering, with an extremely detailed contract, this will reduce the need of a too frequent periodic intervention of the regulator, like the price-cap formula assumes (the "regulatory lag"). But in practice the ever-changing conditions of costs, traffic, investment decisions, technologies etc. make a periodic "adjustment" indispensable.

A capture issues exists here in terms of concentration of the property of the concessionaire: in theory again, if regulation is effective and efficient, it is irrelevant the level of concentration of the property, even to the level of having a single concessionaire in each country, winning all the tenders.

But in practice, as we will see in the next point, the political clout of large or dominant firms can become such as to render very difficult or even impossible an effective regulation (we may say "too big to be regulated", in a perfect logical symmetry with the better known concept of "too big to fail"). This issue, of the risk of excessive political clout, is traduced in the principle of "minimum efficient dimension". It means that if there are economies of scale (per se a good thing in terms of costs), they have to be balanced out in terms of risks of excessive political clout and of reduced contestability of the incumbents when the concessions are tendered out when they expire. (For the Italian network, a recent econometric analysis has found a minimum efficient dimension for toll road concessions to be in the order of 300 km. The dominant concessionaire (Autostrade per l'Italia) is ten times this size. Nevertheless, no action of unbundling the dominant concessionaire ensued, being it protected by a very long lasting contract.)

Seen from the point of view of the concessionaire, there is also a symmetrical risk: a regulator too strong, and therefore able to impose rules and costs in an arbitrary and unfair way. This is known as "regulatory risk", and is something quite real, since it is mainly connected with the variability of the governments, that can well translate in variations of ideology, priorities etc.. It requires national (and sometime international) legislation, guaranteeing full respect of the signed contracts.

In turn, there is an implicit incentive for keeping this risk low, given the fact that if it is perceived by the firms involved to be high, this is correctly translated in higher requested "risk premiums" (see the "admitted level of profit").

Another risk, that concerns the political balance of the regulatory activity, may be called "the winner curse reversed" on the conceding agency. Let's make a practical example: a new, important project of a toll highway in general is charged with heavy political expectations, far over and above its technical rationale (employment, development of an isolated region, etc.).

The concessionaire in charge of its construction is perfectly aware of this, and can rather easily use this knowledge to twist the regulatory conditions in its favor, only with some hints of possible severe delays, or even worse, of a technical impossibility to deliver the project at all. In this context, it has in fact a much heightened political clout.

Some Selected Cases: USA, Germany, an Uncommon Spanish Decision, the Italian Autostrade Case, as an Example of Regulatory Failure

The nation-wide interstate American highway system is without tolls, and it is paid by public money plus by a percentage of the gasoline tax revenue. But being now the network 60 years old, these revenues have become insufficient to guarantee a steady and effective level of maintenance. This paradoxical situation is linked to the extreme reluctance of the American policy makers, at all administrative levels, to tax the car users, that are practically the entire populace, for consensus reasons (this reluctance is extended even to the environment-related taxes, negligible in the USA).

In Europe, Germany is a similar case, but now a very effective satellite-based toll collection exists for heavy trucks. It is aimed to reduce congestion, that is, to allocate traffic in an efficient way, with also a net return for the public purse (the fact that the environment has not been included in the German system is explained by the fact that this issue is fully covered by gasoline taxes, as in the rest of Europe).

Spain has also an extended network of toll roads: it deserves to be quoted here because its regulator has recently decided that an important southern stretch of the network, resulting now fully amortized by the users, has to be set free of any toll, returning within the general free road network that is planned and financed directly by the State.

Let's see now a negative example (very familiar to the author, since he has been directly involved in it): the Italian case (Ragazzi, 2008). At the beginning of the present century, the state decided to privatize the toll network, that was in charge of a public conglomerate, IRI, dissolved by the new European rules on competition and State ownership of industrial assets.

Two severe problems became immediately evident: the first is that the low technological content of the sector was not suggesting any high value-added by the private know-how implicit in any privatization. The second was linked with an equity issue: since the users at that moment had already paid for a high share of the investments, perpetuating a toll system here appeared more an arbitrary taxation than a reasonable policy.

But the worse came with the tendering procedure: nothing similar to a real competition happened, the concession was awarded to the Benetton textile company, that was for sure far away of any technical capability in road management, but very close politically with the governing coalition of that period.

The concession that was given to the Benetton group had both a very long duration, a very high admitted level of profit (WACC), and was based on a “lump sum” regulatory approach, that is, an immediate down payment to the State of 3.5 billion € (about 4 at current prices).

The traffic risk was left to the concessionaire. Several scholars deemed the contract exceptionally favorable, also because the real controlling procedures on the agreed-upon investments and maintenance activities appeared immediately rather ill-defined and weak. (Actually, these scholars had to work on incomplete documents, because the details of the contract were classified, due to a peculiar legal quibble).

The concessionaire was able to repay the down-payment in a very short time, and to reap a handsome level of profit thereafter. The unchecked maintenance generated a series of incidents, culminating in the collapse of a bridge in Genoa with 43 fatalities. The State attempted immediately to cancel the concession, but discovered a clause in the contract that guarantees the payment of the entire expected profit till the expiration of the concession, even in case of severe misbehavior on the side of the concessionaire. A real “pactum sceleris”, that obviously rises the suspect of an extreme form of “capture”, reaching probably direct or indirect corruption. The legal and political dispute now is raging, at the time of writing, and its final results high uncertain.

This example summarizes well a large set of mistakes and capture problems that may well help to suggest a radical and more simple approach to toll road regulation and financing.

An Alternative, Simpler, and Less “Capture-Prone” Model, and its Financing, given also the Low Technical Content of the Road Sector, and the Need of a Consistent Planning Approach for the Entire Network

The main emerging question of toll road regulation and financing must be: it is efficient to put tolls on some roads (given the fact that the majority of roads are not tolled)? That is, to make the users pay for some roads, and the public purse or fuel taxation for the rest of the network? No rationale appears evident here: the collection systems are per se complex (much more than fuel taxation), and even generating traffic slowing down and congestion, if not operated with the latest “free flow” or satellite-based models. Charging strategies are efficient only if limited to marginal costs, that is, wear and tear, and not in general for paying investment costs. The road network is a highly connected and inter-dependent system, that requires a consistent public planning approach. Long-distance traffic is no longer dominant, and the major problems of congestion and pollution are related with short-distance and regional traffic, now even in less-developed countries. Long concessions are prone to generate capture problems in different forms, even in the information sphere. The sector has a modest technical content, and a normally efficient public administration is capable to manage all its main aspects, as proved by the nontoll network.

This said, competition remains an essential ingredient of an effective management of the sector (there is no proof of effective and performing competition taking place in the present concessionary regimes).

The solution seems simple: abolish cost-recovering tolls entirely, re-unify the planning process within the proper administrative levels (regional if possible: both environmental and congestion problems are located mainly here, as well as the related information), and use tolls only in order to internalize the important external cost that is not covered by the gasoline taxation, that is congestion. This nowadays can be made via cheap, flexible, and efficient satellite systems, even “dialoguing” directly with the users. Keep competition pressure on construction activities (as for the nontoll network), and on maintenance by medium-term competitive tendering, avoiding undue dominant positions (see the “minimum efficient dimension” issue).

If the revenues from congestion charging result insufficient, it is really simple either to use some money from the gasoline taxation (In Europe as an average they are well above the external environmental costs in non-urban areas, that is, are by definition inefficient (IMF, 2014)), or rise these taxes up to the necessary level to cover the marginal (or even the average) road costs.

A simple, transparent, contestable system, far less prone to capture than the useless, expensive and cumbersome present concessions-based regimes.

What Constitutes a Megaproject?

The main distinction between a megaproject and the more typical transport scheme is to be found in the outcomes that the promoters anticipate the project will deliver. Transport users are seen as the main beneficiaries of the typical transport scheme. Improvements in safety and in the local environment are also usually identified as benefits that help to make the case for such a scheme. A megaproject is different. Its objectives extend well beyond the users for whom it serves and those others who are directly affected. Megaprojects are intended as instruments of economic and spatial planning policy, with a focus on generating economic growth and creating new urban development (International Transport Forum, 2014). In some cases, the aim is to foster economic growth in the most prosperous parts of a country, maximizing the potential of infrastructure investment and attracting internationally mobile enterprises. In other cases, a megaproject is aimed at boosting growth in one or more of the less productive parts of the country with the intention of rebalancing the economy and contributing to greater social equity. A megaproject often is put forward as a flagship scheme, demonstrating the vision of its promoters and their commitment to implementing change.

Such a definition is, arguably, more relevant than one based on capital costs. It would be perfectly feasible to define all projects with a cost that exceeded some specified limit as megaprojects although there is a risk that, if those projects in this category were afforded some special treatment, scheme promoters would find ways of bundling schemes together to qualify for megaproject status. More relevant is the responsibility of the analyst in providing the decision-maker with an evidence-based assessment of the likely outcomes of the project and the extent to which the policy-maker's vision for the scheme might be realized. In other words, megaprojects are those for which the conventional cost–benefit framework is, on its own, an inadequate means of giving the policy-maker the best possible advice on the likely outcomes of the scheme that are of interest to that policy-maker. In this respect, a megaproject differs from a package of conventional smaller schemes that deliver the more familiar set of outcomes aimed at transport users and those whose health, safety, and environment are affected.

Why have Megaprojects Become a Priority for Policy?

Most megaprojects are aimed at supplying better links between conurbations or making a conurbation more accessible to its hinterland. They are primarily concerned with serving large cities. Over the last few decades, cities and the major conurbations have become increasingly dominant in most countries' economies. Changes in the structure of industry have resulted in service and other sectors that thrive in a dense urban environment delivering an increasing share of economic output. And the resumption of population growth in many cities in the developed world after a long period of decline has put further pressure on urban transport infrastructure, where construction costs tend to be high because of the complexity of urban transport networks. At the same time, the policy-makers in many cities perceive transport investment as a way enhancing the vitality of the city, fostering economic development through integration with well-designed spatial policies, and demonstrating to potential investors the opportunities offered by the city as a place to do business.

Methods for Appraising Transformational Projects

The Standard Cost–Benefit Approach

Cost–benefit analysis (CBA) was developed as a means of ensuring that transport policy-makers had a method for determining priorities between mutually exclusive options and between projects competing for funding. It had the additional advantage of providing the funding department, in most countries the ministry of finance, with evidence from the comparison of the net benefits of the preferred option with the alternative of do-nothing, the reference case, as a means of demonstrating that public money was being spent prudently. And it demonstrated to the wider community, whether parliament or the public, that the overall costs of the scheme, including those imposed on the landscape, on those whose homes were purchased to make way for the scheme, and on others affected, were outweighed by the benefits to transport users and others who provide and consume the goods and services that rely on the transport network. Policy-makers could be satisfied that the implementation of a proposed scheme with benefits in excess of its costs was in the public interest.

Most of the early applications of CBA were to highway schemes because, even in the case of tolled roads, a financial appraisal fails to reflect many of the costs and benefits that follow from the scheme. Techniques were developed over time to extend, define, and quantify the range of impacts included in the appraisal. Changes attributable to the scheme in respect of people exposed to noise, poor air quality, and visual intrusion were quantified and valued in monetary terms, while other nonmonetized environmental impacts were set out as part of the case presented to policy-makers.

Challenges to the Conventional Approach

Toward the end of the last century, the standard approach to CBA faced a number of challenges. Policy-makers wanted to know more about the likely outcomes of a project than was being provided by the standard economic welfare-based method. They wanted to know whether investing in transport would foster economic growth and how any such impacts might be incorporated into the appraisal methods so as to prioritize schemes that would increase productivity. And they also wanted to understand the spatial distribution of the costs and benefits and the role that transport might play in regional economic policy. At the same time, the shift in economic activity toward conurbations, as noted earlier, resulted in an increase in the proportion of the indicative budget to be spent on high cost urban schemes. Policy-makers wanted to use transport investment as a tool of spatial and economic planning.

In the United Kingdom, the UK government responded to these challenges by commissioning a report from the Standing Advisory Committee of Trunk Road Assessment (SACTRA) on the relationship between transport and the economy and on the adequacy of the UK's transport appraisal methods in the context of their findings ([Standing Advisory Committee of Trunk Road Assessment, 1999](#)). SACTRA noted the conditions under which the standard partial equilibrium (PE) cost–benefit methods apply. These include assumptions that prices equal marginal costs in the transport using market. SACTRA identified in their 1999 report the circumstances under which imperfect competition in transport using markets and the associated positive or negative externalities would result in the conventional approach giving biased estimates of the actual benefits.

SACTRA's review of the links between transport and the economy covered the evidence of an econometric relationship between aggregate investment in transport and in infrastructure and economic growth. More relevant to CBA was the emerging understanding of the relationship between agglomeration and productivity and of transport's role in agglomeration, a source of evidence that could be applied at a scheme-based level. SACTRAs also reviewed the recent developments in general equilibrium (GE) and land use–transport interaction (LUTI) models, which provided a possible means of analyzing the impacts of transport on the economy at a more detailed spatial level. However, the UK's Department for Transport concluded in its response to SACTRA that neither GE nor LUTI models had reached a stage at which they might provide an alternative to the PE cost–benefit method.

The Development of Wider Economic Impacts—Augmenting the Conventional Approach

A consequence of the SACTRA report and of research into causes of differences between places in the productivity of their labor force was the addition to the conventional transport appraisal methods of wider economic impacts (WEIs) ([Department for Transport, 2005](#)). The UK's WebTAG guidance, which follows similar principles to those used in many other countries' appraisal methods ([Eliasson et al., 2014](#)), identified three separate types of wider impact (<https://www.gov.uk/.../webtag-tag-unit-a2-1-wider-economic-impacts-may-2018>). Labor market effects are made up of the impact of a change in the costs of commuting. Changes in commuting costs influence people's participation in the labor force, resulting in a labor supply effect. In addition, changes in commuting costs have an effect on the choice of workplace made by people already in the labor force. A second category of impact, induced investment effects, is concerned with the role played by a scheme in changing the location and quantity of new housing and commercial development induced by the scheme and hence its effect on decisions made by firms about the supply and location of workplaces. The third category of wider impacts is made up of an assessment of the changes in productivity on account of the transport scheme resulting in a change in a measure defined as access to economic mass. These wider impacts, including all of the changes in the location of economic activity, have an impact on output and on productivity that forms the core of the additional benefits attributable to a megaproject. For most megaprojects the direct and indirect effects on access to economic mass have made up the largest component of the wider impacts.

Analysis of data on productivity—defined as output per worker—showed a causal relationship between economic mass and productivity ([Graham, 2007](#)). Better-connected cities are more productive places. Thus, investment in transport to improve

accessibility in a city increases economic mass and this results in an increase in productivity, a relationship defined in terms of an elasticity of productivity with respect to economic mass, with the elasticity varying by industrial sector. The analysis also showed that the effect of changes in economic mass on productivity declined with distance from the project, with much of the evidence suggesting minimal productivity effect in places more than around 20 km from the scheme. Improvements in urban connectivity result in more efficient, deeper labor markets with the better matching of people to jobs, opportunities for sharing knowledge between workers and more efficient markets for the goods and services that make up the city's economy.

The measure of access to economic mass is made up of two parts. The first is the change in accessibility or travel costs between that zone and all other zones, with the value of the measure for the other zones each weighted by the number of employees in that zone. This effect has been defined as the static agglomeration effect, in that it relies only on the changes in transport costs. Thus, transport costs are an integral part of the measure of economic mass.

The second is the number of workers in each zone in the city, with the zones often defined so as to correspond with the structure of zoning adopted in the transport model. Cities that have experienced an increase in economic mass induced by a transport scheme tend to benefit from a second-round effect. Workers and firms are attracted from elsewhere and relocate in the city, while existing firms expand because of both the better access to workers, suppliers, and customers, and because each expanding or relocating firm benefits from the increase in productivity from the first-round static agglomeration effect. This second-round effect is made up of two separate impacts. The first is the increase in employment in city center zones, thus increasing the economic mass of the zone. In addition, workers who move to more productive zones benefit from a placed-based effect and tend to become more productive when working in a zone with greater economic mass.

The change in productivity caused by the change in the location of employment is often defined as the dynamic agglomeration effect because it described the impact of a shift in economic activity between places with different levels of productivity.

The effect of the change in accessibility on economic mass, defined earlier as the static agglomeration impact, can be estimated directly from the transport model used to predict the reduction in travel time and congestion experienced by transport users. Estimates of the increase in employment density as a result of the relocation of activity require the use of additional modeling methods discussed in the following section.

Valuing Wider Impacts and Avoiding Double Counting

When establishing a method for valuing these wider economic benefits within the cost-benefit framework, attention has been paid to avoiding any double counting by ensuring that these additional benefits do not include some of the benefits already attributed in the appraisal to transport users. The increase in output per worker caused by the transport investment's direct effect on agglomeration and hence on productivity, the costs of which are already part of the cost-benefit calculation, is counted as an additional welfare benefit. No extra input is required of the workers who benefit from working in a better-connected city, with the opportunities that this facilitates. So the CBA includes both the additional posttax income earned by workers, who get utility from this effort-free increment to their earnings, and the tax they pay on these earnings because society as a whole benefits on the grounds that the other taxes they pay can now be reduced, albeit by a very small amount.

The benefits to workers and firms that relocate to a more productive destination form part of the conventional transport user benefits and are, in any well-conducted cost-benefit appraisal, already part of the transport user benefits. In order to earn this additional income, workers are obliged to change where they work, a change they are induced to make because of the new transport opportunities. Given that they could always have worked in the new location before the scheme opened, the maximum benefit that can be attributed to them is the full amount of the reduction in transport costs, with the most marginal person who moves getting a minimal benefit. Hence the average generated traveler is assumed to gain by half of the benefit of existing users—the well-established “rule of a half.” Their decision to move jobs is based on the trade-off they face between transport costs and posttax wages. As in the case of the first-round agglomeration impact, society benefits from the additional tax revenue on the higher earnings of those who move to a more productive job and this tax revenue provides the source of additional benefit in the appraisal of the scheme.

The method of valuing the agglomeration and other wider impacts specified earlier therefore avoids any doubled counting of these impacts with travel time savings. The agglomeration impacts are positive externalities—benefits derived by society from the actions of individuals in paying higher taxes and in the increased output that is a result of the increased accessibility making all workers more productive without any change in their behavior of the static agglomeration effect. So the PE methods of CBA can be expanded to cover these second-round impacts without compromising the theoretical basis of the method.

In addition, the approach helps to identify the likely spatial distribution of these wider impacts. The assessment of a project, which is based on an appropriate transport model, will show those zones served by the scheme where productivity is increased because of the increase in the access to economic mass. It will also show those places that experience a relative decline in economic mass as workers move to more productive locations and hence are likely to experience a loss of jobs and productivity. Policy-makers have found this information about the likely spatial distribution of the economic impacts of a major project invaluable. It enables them to formulate complementary programs of investment to facilitate the changes in the distribution of economic activity and to respond to any unwanted negative impacts, such as the two-way road effect, whereby a smaller city loses jobs to the larger one when transport links between the two are improved.

Welfare Economics and GDP in Valuing Agglomeration—Two Different Metrics

CBA is founded on the concepts of welfare economics, aimed at maximizing people's utility or the value they place on all the changes related to the transport scheme that affect them. It is not intended to measure the effect of the scheme on the national economy, defined in terms of GDP, a metric that is restricted to marketed goods and services. Impacts such as savings in travel time on leisure trips or environmental impacts figure in the cost-benefit methodology but are not part of the conventional national GDP accounting process.

However, most governments have an objective of raising productivity and so of increasing GDP as an indicator of the growth in a country's prosperity (Vickerman, 2017). One of the strengths of the appraisal of the wider impacts of a transport scheme is that these acts can be valued either in the context of a welfare cost-benefit framework as described earlier or in terms of GDP and national accounting methods. The increase in output per worker is caused by the transport investment, the costs of which are already part of the cost-benefit calculation. No additional input is required of the workers who benefit from working in a better-connected city, with the opportunities that this facilitates. As noted earlier, CBA includes both the additional posttax income earned by workers and the tax they pay on these earnings from which society as a whole benefits. The additional pretax earnings of workers which can be attributed to the scheme will be counted in a country's national accounts as a measure of increased productivity and hence as an impact on GDP. In this respect, the welfare impact and the GDP effect are identical.

The additional earnings generated by relocation are treated differently between a CBA and a GDP metric. As noted earlier, the welfare benefit gained by those who change where they work are measured through the change in transport costs they experience, with the most marginal person who moves gaining a minimal benefit and hence the average traveler who moves jobs getting half of the benefit of existing users. Added to this is the social benefit from the additional tax revenue on these higher earnings. But the GDP metric counts the entire increase in output since the additional commuting costs or the additional demands on the worker when in the higher paid job do not count as costs in the GDP calculus to be offset against the increase in productivity.

Estimates of the GDP effect have helped decision-makers understand the potential for raising funds for major projects. Such estimates can show the extent to which the initial capital costs might subsequently be recovered through tax payments on the additional income generated by the changes in the location of economic activity caused by the project. An analysis of the GDP effects of London's Crossrail scheme helped to make the case for the introduction of the business rate supplement, an additional local tax which has been levied on all large firms in London and which provides around a third of the funding for the scheme.

Estimating the Relocation of Economic Activity Using General Equilibrium and Land Use–Transport Interaction Models

Various approaches have been used to model those impacts of transport schemes that fall outside the first-round effect of a change in generalized costs experienced by transport users. There are two broad categories of approach—one based on GE modeling and the other on LUTI models. Both serve to provide estimates of the impact of a major transport project on the location of economic activity.

Spatial Computable General Equilibrium Models

The GE approach is aimed at modeling the whole economy with some level of spatial detail in the case of it being applied to transport schemes. It provides a coherent account of trade, production, investment, and employment. The approach makes projections of these key variables at a national and regional level both in a reference case and for a range of scenarios for different policy interventions and external shocks. The methods used are capable of representing key relationships, including those between accessibility, the location of employment and of households, and the impact of location on productivity. GE models can also represent the role of the public sector and the interaction of tax revenues, public expenditure, and interest rates. GE models have proved their usefulness over many years in considering policies relating to trade and taxation, accounting for the multiplier effects of income on employment and subsequent responses in the economy.

Spatial computable general equilibrium (SCGE) models are primarily aimed at providing estimates of the change in the level and broad location of economic activity as the result of a change in policy. The method has been adopted to provide decision-makers with estimates of the effect of a scheme on local and regional employment and on productivity. In this respect, the analysis has been used to give decision-makers an alternative measure of a transport scheme's expected outcomes which is relevant to wider policy objectives and provides additional context to the conventional benefit-cost ratio. GE models can deal well with the comparison of the reference case with the project: their completeness ensures that they can distinguish between effects which are a net addition to economic activity and those which are no more than a change in the location of a given level of activity. Such distinctions are often left to judgment in the PE approach framework.

SCGE models have seen only limited application in the United Kingdom. They have been used by the UK's Department for Transport in the appraisal of the Lower Thames Crossing, a scheme with an objective of reducing transport costs as a means of improving the efficiency of labor markets in north Kent and in Essex and by the UK's Airports Commission to assess the impact of runway capacity on productivity and employment. In these two examples, the model was used to provide estimates of the net impact of the project on regional and national employment and GDP impacts. It also provided estimates of the dynamic agglomeration impacts as an input into the modified PE method of estimating dynamic agglomeration impacts described in the section earlier.

Land Use–Transport Interaction Models

LUTIs have been used for many years to demonstrate the impacts of the changes to land use that are likely to result from the changes in accessibility that follow from a transport scheme ([The London Land Use and Transport Interaction Model, 2014](#)). Since such changes generally depend on land-use planning consent, the models have been used to inform scheme promoters and land-use planners about the pressures for land-use change and the consequences of such changes on traffic flows, the environment, and on local services.

LUTI models represent the responses of households, employers, and developers to changes in accessibility measured through changes in transport costs. In order to estimate such responses, the models include data on all other costs, including rents and wages, incurred by firms and households and on the interaction between agents in the model. As a consequence of this framework, the LUTI approach has been extended into a model of the local, regional, or national economy that shares many of the characteristics of the full GE approach while generally providing a greater level of spatial detail. It is not as comprehensive—for example, LUTI-based models tend to lack a government sector and so government spending does not crowd out or otherwise affect private sector investment. And, because the economic model contains less spatial detail than the transport model that serves the purpose of informing the design of the scheme, the modeling framework makes use of a simplified and cruder version of the latter.

An appropriate LUTI model will incorporate information on local planning permissions and can help to demonstrate the extent of any potentially profitable development which is dependent on the scheme, thus helping to bridge the gap between aspirations of the scheme promoters and likely market forces. The credibility of the model's predictions of the location and level of transport-induced development is strengthened by the inclusion in the model of these estimates of the costs and profitability of development.

Integration of the Broader Approach with the Partial Equilibrium Appraisal Methods

Neither these approaches provide, in their present form, a complete alternative to the PE approach for estimating welfare benefits. While they are used for estimates of the dynamic agglomeration benefits of the move to more productive jobs, the conventional transport user benefits are derived from the relevant appraisal values, such as values of time saving, and from the changes estimated in the transport model. There is therefore a potential inconsistency between the benefits derived from the conventional PE method, which is based on assumptions of fixed land use, constant returns to scale, and perfect competition in the markets for goods and services which make use of the transport network and the wider impacts estimated in the SCGE or LUTI-based supplementary economic models.

As with all such models, the assumptions made to generate these predictions of land-use change, while based on the best available estimates, remain very uncertain. The parameters in the model that represent the many responses of agents to changes in transport costs and in the associated costs of doing business in different locations are taken from a wide range of sources of differing levels of reliability and in some cases are based on the modeler's judgment. There have been cases in which predictions of a scheme's impact on GDP have exceeded, by an order of magnitude, the estimates of the welfare benefits despite the latter taking account of leisure transport user time savings and other benefits omitted from the GDP metric. Such cases tend to assume a significant level of spare capacity in the economy that will be brought into productive use through a multiplier effect acting on the agglomeration-related increase in output. Yet predictions of the level and spatial location of unemployed resources in the economy 10 or 15 years hence when eventually the scheme opens are highly speculative.

The United Kingdom has followed the practice of using spatial economic models to give estimates of the change in the location of employment as a means of estimating the dynamic agglomeration impacts of a major transport project. Assumptions about the relationship between productivity and economic mass are taken from the extended PE approach described earlier. And, as described earlier, the effects of the relocation of economic activity can be expressed either in terms of the conventional welfare economics metric or as an increase in regional or national GDP.

Conclusions

The methods described earlier go some way toward providing decision-makers with the additional information they need about the likely impacts of megaprojects. And the facility to give an estimate of a scheme's impact on regional and national GDP significantly increases the value of evidence-based analysis in the eyes of decision-makers. Nevertheless, these modifications to CBA have a number of limitations. The wider impacts approach is best suited to estimating the effects on a single agglomeration: it is less well able to model the effects of a scheme which connects two or more potentially competing urban areas by showing whether greater specialization might be a result of such a scheme. Nor does it address the potential impacts on the freight and distribution sectors of major improvements to highway networks.

The methods tend to show that the benefits of a megaproject are greatest in more prosperous and productive places. They do not go very far in helping analysts give advice to decision-makers on whether or how transport investment might promote the development of those parts of cities or regions that have experienced economic decline.

Nevertheless, structure and form of the model provides a more disciplined method of understanding likely outcomes and the forces that influence these outcomes than an assessment made without such a framework. A better understanding of the likely changes in the location of jobs and of workers makes it possible for policy-makers to plan other complementary measures to

facilitate the changes and to minimize the disruptive effects of a major scheme. For example, a LUTI-based economic model can show how a major transport project will affect the market for housing in the places it serves and the extent to which any offsetting influence of rising house prices on employment and productivity might be mitigated by the release of more land for house-building. And the approach can also show, through the use of a detailed urban transport model, the role of improved local transport links needed to distribute users of the megaproject across the urban center.

Introduction

Transportation has always been risky. Our ancestors faced risks from being thrown from horses or drowning in rivers. The mechanization of transportation increased the forces exerted on the human body when something goes wrong. Mass transportation increased the number of possible casualties in any incident. Private grief becomes a public spectacle.

Highway transportation is particularly risky. The World Health Organization reports that highway crashes are the eighth leading cause of death with 1.4 million annual fatalities. (Note that safety professionals prefer the word “crash” to “accident” because the latter suggests that occurrence is due to pure fate and cannot be influenced by human decisions.) The per capita risks in low- and middle-income countries are 3 times higher than in the safest countries in northern Europe despite relatively low levels of motorization. In contrast, the risks on railways, waterways, and airways are much lower. But incidents in these modes attract considerable public attention relative to highway crashes.

Economics and Engineering

The proximate cause of crashes is an interaction between vehicle operators (riders, drivers, pilots, etc.), their vehicles, and the infrastructure (highways, railway track, waterway, airway, etc.). For highways, the matrix by Haddon (1972) categorized the factors that explain crash causation and consequences. This three-by-three matrix has the driver, the vehicle, and the highway on one axis, and factors that occur prior to a crash, during a crash, and after a crash on the other axis. This matrix along with illustrative factors is shown in Table 1. While this matrix is specific to highway crashes, clear analogies can be made to other modes.

Economics is a complement to, and not a substitute for, the work of human factors and engineering professionals. Economics is important because, long before a crash occurs, drivers have made decisions on how aggressively they drive and how well they maintain their vehicles. Bus and trucking companies have decided on employee training. Highway engineers have decided on design characteristics of the road. The legislature and police authorities have set traffic laws and decided on how aggressively to enforce these laws. Public bodies have decided on budgets for the provision of first responders and trauma centers.

Each of these actors has made decisions by comparing the benefits and costs of their actions. To an economist, the “safety problem” emerges because their decisions do not accord with the best interests of society as a whole. There are “too many” crashes.

Table 1 Haddon's matrix

	<i>Before the crash</i>	<i>During the crash</i>	<i>After the crash</i>
The driver	• Conduct (speed, etc.) • Skills • Vehicle maintenance	• Use of active safety devices (fastening of seat belt prior to the trip, use of child safety seat)	• Skills and equipment of first responders
The vehicle	• Design • Safety equipment • Collision detection • Collision avoidance	• Energy absorption • Cabin design • Passive safety devices (air bags)	• Ease of extraction from vehicle • Integrity of fuel and battery systems
The highway	• Design • Materials • Maintenance	• Guardrails • Breakaway sign posts	• Ease of access by first responders • Location of first responders and trauma centers

Economists describe this as a market failure. By understanding why actors do not act in a socially optimal way, interventions can be designed to persuade actors to modify their behavior and ameliorate the market failures.

How Safe is Safe Enough?

Crashes are undesirable, yet costly to prevent. While society cannot afford to eliminate all crashes, it certainly would prefer that there are fewer crashes than there are today. Determining exactly how many crashes are acceptable to society is difficult. However, understanding the process that actors go through in determining safety provides insights that are useful when designing interventions in the market.

Socially Desirable Decisions by Private Users

Models of safety determination fall into two broad categories. The first category is models of private users operating their own vehicles. This category includes:

- automobile drivers;
- motorcyclists;
- pedal cyclists, pedestrians, and other nonmotorized road users;
- pilots flying their private planes; and
- recreational boaters.

Private users invest money, time, and effort to reduce risks. They invest in their skills, purchase vehicles with more safety features, and pay for maintenance. They can conduct themselves cautiously, perhaps at a cost of taking longer for their trip. This can be referred to as preventive effort. Users trade off these costs against a reduced probability of a crash or increased survivability in the event that a crash occurs. In making their decisions, they adjust for the state of the infrastructure and their assumptions about the effectiveness of emergency response.

While all users prefer more safety to less safety, they may vary in their prevention costs (thrill-seeking users find it more costly to act cautiously) and the magnitude of the losses in the event of a crash (e.g., the losses incurred by a head of household vs. a single person). Consequently, users may rationally exercise different levels of prevention and hence have different safety outcomes.

The variation in safety outcomes is not necessarily a market failure. However, choices are only socially desirable if actors are (1) fully informed about the cost of preventive actions, (2) are aware of the consequences of their actions on crash occurrence and survivability, and (3) are responsible for the full consequences of any crashes that they cause, including damages to other users and bystanders.

Socially Desirable Decisions for Commercial Carriers

The second category of models describes markets where passengers and freight shippers contract with a commercial carrier. Examples include:

- taxis, buses, and other forms of public highway transportation;
- trucking;
- rail passenger and freight services;
- passenger and freight airlines;
- maritime companies; and
- pipelines.

There is a principal-agent problem in that while passengers and shippers have preferences for the level of safety they are willing to purchase, it is the carriers' conduct that produces safety outcomes (Maurino et al., 1995). Passengers and shippers have to select a carrier whose safety matches their own preferences.

Commercial Passenger Transportation

Carriers expend preventive costs to lower the safety risks. While at low safety levels, expenditures on prevention may result in a reduction in total costs due to fewer crashes; in general, carriers that offer higher safety have to charge higher fares to break even. Passengers with a high valuation of safety, and the ability to pay the higher fares, gravitate to carriers offering higher safety. A vertically differentiated market may exist with high safety—high price carriers coexisting with low safety—low price carriers. Often, a variety of safety levels in the market are seen as an indication of market failure. But this is not the case if passengers vary in their tastes for safety, and are able to recognize the safety level offered by different carriers.

Commercial Freight Transportation

Shippers of freight look to minimize the cost of transporting their goods. But in doing so, they have to trade off the costs of more safety with the consequences of any crashes that occur. Because different commodities have different costs of handling and cause different levels of harm in the event of a crash, it is likely that safety varies by type of commodity. Delicate cargoes and those that present high hazards in a crash are handled with considerable care, and more robust and benign cargoes move at lower levels of safety. As with passenger transportation, the variety of safety outcomes does not necessarily indicate a market failure. But socially desirable decisions depend on shippers being knowledgeable about the level of safety on offer, and on carriers, and hence shippers, bearing the full consequences of crashes. The latter is particularly important for hazardous materials, where releases can harm bystanders.

Socially Desirable Decisions by the Infrastructure Providers

In vertically integrated modes such as pipelines and railways, carriers also control safety of the infrastructure. In aviation and maritime, commercial and private users depend on decisions made by ports and airports, and traffic control services. But the distinction is most stark on roads. Design and maintenance of the highway is crucial to system safety, yet there is a separation between the highway authority and the users.

How should the highway authority decide on appropriate design? Economies of density and scale mean that there are a limited number of roads between two places, and a common highway authority presides over the entire network. Consequently, a “one-size-fits-all” level of safety is offered to all users irrespective of their safety preferences. In an ideal world, the authority would select a level of safety that provides the greatest amount of social benefit. This level may not sit well with users who desire a higher level of safety, and those users who would prefer the lower user fees associated with a lower level of safety. There is already a market failure inherent in road provision associated with imperfect competition or monopoly.

Socially Desirable Decisions by Emergency Responders

An often-underestimated way to improve safety is better emergency response. Prompt medical attention during what is called by emergency physicians the golden period (often about 60 minutes) after trauma occurs can be crucial in preventing fatalities. Prompt response to crashes involving hazardous materials can be crucial in mitigating harms to people and property. As with highway infrastructure provision, a “one-size-fits-all” approach is necessary recognizing that emergency services and trauma centers serve other hazards in addition to transportation crashes.

Summary of Desirable Decisions

To summarize the discussion thus far, if transportation users (1) are fully aware of the risks, (2) are fully aware of the costs and benefits of mitigating the risks, and (3) voluntarily accept the risks to gain the benefits of mobility and economic opportunity, then there is not a “safety problem.” Moreover, safety outcomes can vary between individual private users and various commercial carriers. This results from variations in willingness to pay for safety by private users and passengers, and variation in the safety prevention costs and harms caused for freight commodities. High safety may optimally coexist with lower levels of safety in vertically differentiated markets. To an economist, this is an indication that the market works and does not necessarily indicate a market failure.

Why the Market Fails

The underlying relationships that describe the socially desirable outcomes are difficult to measure. Calculating the optimal levels of safety in a particular mode is not trivial, and may be practically impossible. However, there are extensive failures in the market for safety. These lead to many actors exerting less preventive efforts than is socially optimal. Consequently, a productive role for public policy is to identify the extensive market failures and devising interventions to ameliorate or correct them. This may be more productive than agonizing over estimating what the level of safety “should be.”

The failures derive from the following three underlying characteristics of safety:

- For most actors, the beneficiaries of their preventive efforts include other actors. Unless they are altruistic, this leads the actor to underinvest in prevention because they reap only part of the benefit. Economists call this an uncompensated externality.

- The costs of prevention are incurred in the present and are incurred on every trip. The benefits of reduced crashes do not occur on every trip and only happen at randomly determined points in the future. Actors may discount these future benefits and underinvest in prevention in the present.
- Unlike characteristics such as price that are readily observable, actors may be poorly informed and may purchase a product and service that does not match their tastes in safety. This is because safety is a probabilistic attribute and may not be observable on every trip. Moreover, other actors might avariciously take advantage of poorly informed purchasers by selling a low safety product at a price that is consistent with higher levels of safety.

Externalities

Safety externalities are abundant. Injuries are sustained by innocent vulnerable road users struck by motorized vehicles. Bystanders are affected by hazardous materials releases. Legal structures have developed to assign fault and recover damages. But, they are not a panacea. There may be limitations on the harms that can be legally recovered, and victims may find that the responsible party does not have the financial resources to pay compensation.

Bilateral Crashes

While a surprisingly large number of crashes involve a single vehicle (e.g., a motor vehicle running off the roadway), collisions with other users predominate. The actions of both parties determine the probability of a crash. A complex legal literature describes how fault should be assigned to ensure that the actor who can reduce the risk at the lowest possible cost should be given incentives to take action (Shavell, 2004). Market failures abound in the adjudication of fault in multi-vehicle crashes.

Cognitive Failures by Individuals

Private users make decisions to expend effort to mitigate risk in the present, but the consequences of their actions or inactions occur in the future. Passengers have to choose between the level of fares and future crash risks. Some individuals may be myopic in ignoring or downplaying the future consequences. Others may lack self-control when trading off effort in the present with future negative consequences. More broadly, humans tend to be very poor in evaluating the probability of low-probability crashes, and thinking about the consequences of deadly events. There is considerable overconfidence, with the majority of drivers believing that they are safer than the average driver, which cannot be true statistically. Individuals also suffer from cognitive dissonance in that nearly all trips are completed safely reinforcing beliefs that a crash “will not happen to me.” As a result of this range of cognitive failures, users downplay the future probable benefits from investing in safety in the present. They take less care than they should.

Imperfect Information

While fully informed actors can have cognitive problems in processing information, the problem is compounded when actors are poorly informed. Private users may be poorly informed about the safety characteristics of their vehicles and the magnitude of the potential safety benefits from modifying their conduct. The situation is even worse for commercial transportation. Passengers and shippers have to form an opinion about the levels of safety that carriers are offering. Unlike other attributes of service such as price and speed, information on safety is difficult to observe, obtain, or understand. Crashes are rare events and tend to be a poor indicator of the safety of individual carriers.

Vertically differentiated markets require customers to sort themselves among the safety offerings, and this is difficult when information is poor. If customers are totally uninformed, all carriers offer a low level of safety. Carriers would be unable to convince customers that they are offering a high level of safety with a commensurate higher price. Therefore, differences in safety offerings indicate that customers are at least partially informed. Albeit, poor information is endemic in safety markets.

Carriers also suffer from imperfect information. Carriers rely heavily on the skills of their employees to produce safety. Yet, they are imperfectly informed about their skills at the point of hiring, and frontline employees tend to perform their duties without direct supervision. Especially in commercial road transportation, drivers with poor safety records can successfully masquerade as having higher skills in order to work at carriers who pay higher wages and wish to provide a high-quality product.

Carrier Myopia

As with private users, some carriers may be myopic in that they downplay the future consequences of their current actions. They may be very well aware of the costs of employee training but do not appreciate the beneficial effect on future crashes. This failure is particularly associated with inexperienced new entrants to the market.

The problem also extends to incumbent carriers. If passengers and freight shippers are imperfectly informed, then conditions are ripe for some carriers to cheat. Carriers that previously offered a higher level of safety could cut their safety investments (and hence their costs) while still masquerading as a higher-safety carrier and charging a high price. Such carriers can earn profits, at least until the customers find out and either shun the carrier or demand a lower price. Why might a carrier do this? Carriers close to bankruptcy

may be particularly susceptible. The carrier may hope that the cost savings provide a buffer until favorable trading conditions return. Other financially stressed carriers may discount the future consequences of crashes because they know that they do not have the finances to meet any judgments.

Economists tend to be skeptical about such arguments, because a carrier has invested to obtain a reputation for high quality. Why would such a carrier want to squander its reputation? Nevertheless, cheating tends to be very prevalent, and has severe consequences. Customers end up purchasing a service that differs from their tastes, and, in the event of a crash, the carrier may not have the financial resources to pay compensation.

Imperfect Competition

The market failures due to lack of choice in modes with economies of density and scale have already been discussed. Even in inherently competitive modes such as highways, a “one-size-fits-all” level of infrastructure safety results in a market failure. When there are few competitors, a small number of safety choices are available in the marketplace, and most passengers and shippers cannot obtain the exact level of safety that they desire. In commercial modes indivisibilities in vehicle size (airplanes, trains, and less-than-truckload trucking) mean that customers with different tastes in safety share the same vehicles, and a limited number of safety options are on offer.

Relative Magnitude of the Market Failures

The applicability and magnitude of the market failures varies significantly between modes and between private users and commercial passenger and freight services. **Table 2** provides a summary using a star rating of the relevance of the six market failures to the various modes and market segments. The more stars indicate the more prevalent market failures.

Market Interventions

Recognizing how the market failures originate and which actor(s) they affect is the basis for intelligent public policy prescription. Policy responses need to be tailored to the root causes of the problem, and the actor who can most effectively change the market outcome. No intervention is a panacea by itself, and some interventions have their own weaknesses. Consequently, these interventions should be thought of as complements and not substitutes.

Liability

Externalities and bilateral crashes are directly addressed by making responsible parties legally liable for their actions (Shavell, 2004). Liability is a powerful solution to these problems but it is not without limitations. The law may limit some losses from being recovered (e.g., emotional harm or lost profits as opposed to physical damage). It is also an “after-the-fact” market intervention. Private users and commercial carriers who are myopic may still underinvest in safety, even if they ultimately have to pay compensation.

Insurance Requirement

Insurance goes hand in hand with liability because of the concern that a responsible party may not have the resources to satisfy claims (Dionne, 2014). Insurance also tackles the problem of myopia by transforming future consequences into premiums that have

Table 2 The magnitude of the six market failures by mode

^aFailure comes from the provision of highway infrastructure.

to be paid in the present. Private users and commercial carriers can trade off greater safety investments against reduced premiums in the present, and there is less chance of myopia. Insurance companies also have incentives to monitor the activities of their clients, and this gives incentives to insured parties not to shirk on preventive efforts.

All insurance suffers from two main drawbacks. Moral hazard occurs when an actor covered by insurance acts in a riskier fashion than it would do otherwise because the insurance company is responsible for paying any claims. If insurance is optional, there are problems of adverse selection when low-risk clients opt not to purchase, and premiums increase as only higher-risk clients remain.

Information Provision

The obvious solution to imperfect information is making actors better informed. New private users and operating employees of commercial carriers are typically required to take classes and pass a test before receiving a license. The classes and tests focus on understanding the risks and rules of conduct. Subsequently, users are bombarded by public information campaigns warning of the consequences of fatigue, distraction, and alcohol.

Information can be provided to passengers and shippers to help them decide which carrier to select. Rating schemes can be put in place by the government or private providers. This is unambiguously a good thing, as customers become aware of which carriers offer poor service, and the customers provide a discipline on the market. However, such information cannot deal with the problem of cheating. Cheating carriers deviate from their past safety performance. Retrospective information on crashes may not be a reliable prediction of future performance. It is often argued that information should be provided on safety inputs, such as employee training, as opposed to safety outputs (crashes) as a predictor of future safety performance.

Safety Regulation

A familiar intervention is setting and enforcing minimum standards. These standards can be on user training and conduct, the safety features of vehicles, infrastructure design, emergency response, and management processes adopted within commercial carriers. These regulations only define a minimum. Users and carriers are free to adopt higher safety levels if they prefer. Therefore, safety regulation is not a good solution to the problems of imperfect information in passenger and freight transportation because it does not inform customers about the range of safety that is offered. For mode specific details, see [Elvik et al. \(2009\)](#), [Evans \(2004\)](#), [Kristiansen \(2005\)](#), [Lamm et al. \(1999\)](#), and [Savage \(1998\)](#).

A common regulatory concern is known as risk compensation ([Blomquist, 1988](#)). This is when a user or carrier compensates for regulatory action in one dimension by undertaking riskier actions in another dimension. For example, making a highway less risky by straightening curves may encourage road users to drive faster. This is not an argument that regulatory action should not be undertaken, but rather that the consequences of regulatory action may be overstated.

There is a tension between expressing the minimum as a specification standard or a performance standard. In many ways, a performance standard that specifies the required safety outcomes best addresses market failures and does so without the regulator micromanaging the production of safety. In practice, standards are often expressed as minimum technical specifications for user conduct and vehicles, as these form bright line rules for the determination of compliance and the assessment of penalties.

A regulatory approach requires a legislative framework to enact regulations, and then an enforcement strategy by the police, government inspectors, and the courts. In setting a minimum standard, there is a risk that the standard is either set too low or unreasonably high. Economists have long used a technique called benefit–cost analysis to help determine the level at which the standard should be set. This is combined with quantitative risk assessment techniques that attempt to estimate the effects of actions on the number and severity of crashes. The costs of the regulation are compared with the expected benefits. Purely financial costs and benefits are combined with monetarized equivalents of costs such as longer journey times and benefits such as reduced injuries ([Jones-Lee and Spackman, 2013](#)).

Regulations are meaningless unless they are enforced. Forming a strategy for regulatory enforcement is not trivial. For example, there is a trade-off between the probability of detecting a violation of the regulations and the size of the resulting penalty. There can either be a high probability of detection and a low penalty, or a low probability of detection and a high penalty. Users might also be rewarded for good conduct in addition to penalizing poor conduct. It is an empirical matter as to whether enforcement is effective in changing behavior and preventing recidivism.

Closing Comments

Safety is an important and contentious aspect of transportation. The annual number of fatalities and serious injuries is large. So is the amount of property damage and the potential harm to the environment. The provision of safety is riddled with cognitive and market imperfections. Corrective legal and regulatory interventions are longstanding and continue to evolve. Despite substantial improvements in the past half-century, society continues to demand that more should be done to further reduce the risks.

Introduction

Cost overrun of transportation infrastructure projects is a topic that has attracted the attention of academics, decision makers, the media, and the public at large. For instance, in the last four decades, a plethora of scientific papers and audit reports have been written; most of them attest to large overruns (for a review of the literature, see [Odeck, 2019](#)). The media has reported hundreds of headline reports of large overruns. Interestingly, the interest in cost overruns by their stakeholders seem to be different. The academics seem to be interested in measuring the magnitudes of and finding explanations for overruns, while decision makers are more interested in finding ways to reduce the size of overruns. However, the public regards the large magnitudes of overruns as a dishonest practice, where the taxpayers' money is misused by the decision makers.

Although cost overrun is frequently addressed in the literature, there appears to be no common understanding of its basic concepts available in a single source. Such a common understanding, if available, may help in finding ways to eradicate overruns. As matter of fact, disagreements in the literature have occurred regarding both the appropriate measure of overruns and what measures can be taken to reduce their magnitudes ([Flyvbjerg et al., 2018](#); [Love and Ahiaga-Dagbui, 2018](#)).

The aim of this article is to provide a comprehensive and common understanding of the concepts of cost overrun in transportation infrastructure projects. We do so by suggesting answers to the following questions: (1) What is a cost overrun of a transportation project? (2) What problems do overruns cause for stakeholders? (3) How should overruns be measured? (4) How common and prevalent are overruns worldwide? and (5) What are the potential ways of avoiding overruns? The rationale of this article is to provide a brief and comprehensive overview of these important issues.

The remaining part of the article is organized as follows. In the next section, we define the concept of cost overrun, why overruns arise and the problems that overruns cause for stakeholders. In the third section, we describe the different alternative measures of cost overrun and suggest when these measures are useful to consider. The fourth section addresses how prevalent cost overruns are worldwide. The fifth section provides some concluding remarks and discusses potential ways of reducing overruns.

The Concept of Cost Overrun

When addressing issues surrounding cost overrun, a clear and a common definition of the concept of cost overrun must be provided because it can be understood and measured differently, depending on how it is defined. Cost overrun is a term often used in the context of any construction project when the actual cost is greater than the budgeted cost. It is thus a measure of the difference between the actual cost and some budgeted/estimated cost, given that the difference is positive. Consequently, if the difference is negative, then "cost underrun" has occurred, and if the difference is zero, then the actual cost exactly matches the budgeted/estimated cost, and neither overrun nor underrun occurs.

Note that if a cost overrun occurs and a budget was used as the base of comparison, then the cost overrun is sometimes referred to as a "budget increase," "cost increase," or "cost growth." Cost overruns should, however, be distinguished from another related term, "cost escalation," which is used to express an anticipated growth in the budgeted cost due to factors such as inflation.

So far, we have defined cost overrun as only the difference between the actual cost and some budgeted/estimated cost in absolute terms. We revert later to its different measures, for example, relative measures, and what those measures tell and which estimates/budgets should be compared to actual costs given that there are often many estimates/budgets throughout a project's planning process. Thus in the next two subsections, we first discuss (1) the problems of cost overruns and (2) why overruns occur.

What are the Problems of Cost Overruns?

Given the definition of cost overrun earlier, that is, that it is the excess of the actual cost over the estimated/budgeted cost, a natural question to address is what problems it causes for the decision makers who sanction projects, the public, transport system users, and the practitioners who make cost estimates. Although the magnitudes of cost overruns of transportation projects have been attested to be prevalent and, in some instances, exceptionally large, the real problems that they cause for stakeholders are less frequently addressed.

Large cost overruns are a problem for decision makers who, based on the cost estimates provided to them by estimators (i.e., practitioners) and given their limited budgets, rely on those estimates to allocate funds for different projects. The immediate problems that arise for decision makers if cost overruns are large and prevalent are therefore as follows: (1) they burden decision makers with unexpected expenses worth hundreds of millions euros/dollars, (2) they put the financial viability of projects at risk, where projects may be stopped and/or their implementation extended and/or delayed, which *ceteris paribus* implies that transportation infrastructure users will wait longer to realize the benefits, (3) the decision makers may be forced to crowd-out funds that could have been used for other more needy investments, and due to (1), (2), and (3) above, the decision-making process may lose legitimacy and trust in the eyes of the wider public. A fourth problem of cost overrun for decision makers, as mostly observed by transportation economists/planners, is that overruns may lead to the incorrect choice/ranking of projects against other projects competing for limited government funds. This occurs because transportation economists correctly argue that projects should be chosen according to how high their benefit-cost ratios (BCR) are, that is, the ratio of a project's net benefits to its financial costs funded by a government budget. A higher BCR results in a project being more beneficial to the society. In this respect, the problem of cost overrun is that it may initially depict a project as having a high BCR and, hence, cause it to be chosen, while if overruns (when correct estimates are provided) are accounted for, the project has a low BCR, that is, the value of the numerator should have been higher, leading to a lower BCR; therefore, the project should not have been chosen over others or not funded at all given that funds are limited. Hence, the decision makers fourth problem with cost overruns is that it misleads them into make incorrect decisions, and less beneficial projects may be chosen over those that are more beneficial. It should, however, be noted that proponents of benefit-cost analyses (BCA) with BCR as a ranking criterion do not argue that it should be the only base for decision making. They actually argue and accept that there may be other factors not captured in a BCA such as nonmonetized and distributional impacts that may matter for decision makings. What they presuppose, however, is that the use of CBA would increase the benefits for tax payers if it had some influence on the projects ranking/selection.

Note, however, that large cost underruns are also a problem for decision makers. Had the correct estimates been provided, overestimated funds could have been used to realize other profitable projects at a much earlier stage so that users of facilities would benefit much earlier. This problem is, however, not as critical as the aforementioned ones.

For the practitioners, that is, engineers and economists who make the cost estimates, the real problem with cost overruns is that these practitioners lose their credibility as experts on cost estimation.

The problem of cost overrun for transport users and the public at large has been touched upon earlier. In cases of large and frequent overruns, the public will have a perception of misuse of public funds and, consequently, may punish the decision makers, who generally are politicians, by voting them out in the next election. For transport system users, cost overruns are a serious problem in terms not being able to use the transport system in a timely manner as planned, and projects may be postponed or not built at all because the planned funds are redirected to overrun projects. Since most transport infrastructure projects are built as a means of reducing transportation costs for system users, overruns imply that system users continue incurring greater transportation costs than necessary.

The problems of cost overruns addressed earlier, if added together, should verify why academics, the media and decision makers are wary of cost overruns in the transportation sector worldwide. It should be reminded here, as previously explained that cost underruns are also a problem, although not as grave as overruns.

Why Cost Overruns Occur

The next question worth addressing, which should succeed the former question addressed earlier, is why do cost overruns occur given that they cause such problems? A plethora of papers in the academic literature have sought an explanation for why cost overruns occur, but no one conclusion has been derived; instead, several explanations exist, some of which are true, while others are more of speculations than facts. Further, we address the most frequently used arguments in the literature for why cost overruns occur.

The most frequently stated reasons for cost overruns in the transportation literature, which can be classified in three categories according to Flyvbjerg et al. (2002), but which we expand on and explain, are as follows: (1) psychological, (2) political economic, and (3) technical/economic. The psychological causes of observed cost overruns are explained as optimism bias or man's inherent optimism, that is, those who make cost estimates are optimistically biased, a phenomenon known to exist among human beings regarding future outturns of their present undertakings. In relation to infrastructure projects, this means that cost estimators tend to think highly of themselves in that their estimates are at less risk of incurring overruns than others.

The political-economic reason for observed cost overruns is that, due to pressure from interest groups, for example, politicians, project promoters, contractors, etc., those who make cost estimates are driven to deliberately underestimate cost to make the estimates more acceptable to interest groups or decision makers.

Technical/economic causes of cost overruns involve information that is not available at the time of cost estimation, such as price escalation of unit variables, changes in the design and scope of a project (change order), ever emerging new regulations (e.g., environmental demands that are costly), and pure estimation mistakes (e.g., failure to account for certain and already available information provided by engineers such as transportation costs associated with removing and depositing volumes of masses removed from tunnels/roadways or accounting for masses and their transportation costs required to fill the dugs to ascertain frost free roadway surfaces).

Another, but less cited explanation of cost overrun, is that of Eliasson and Fosgerau (2013) who claimed that *selection bias* may occur whenever ex ante predictions are related to the decisions on whether to implement a project or not. However, they argued that even if ex ante estimates are very uncertain the selected projects will turn out to perform better on average than random projects. Moreover, as they rightly pointed out, one cannot conclude based on the observation of ex post bias that there must have been bias in the prediction's ex ante. The reason for which is that the unselected projects may have been equally biased.

Although the aforementioned described reasons may be the causes of cost overruns, no clear-cut empirical evidence; a proof without doubt, has been provided in the literature to prove that reasons (1) and (2) exist. Hence, we contend that they are unsubstantiated but are possible reasons for overruns. Reason (3), however, has been proven in the literature to apply when certain information is not available at the time of cost estimation, thereby leading to cost estimates being lower than actual outturns. We discuss later how cost overruns can be avoided while reflecting on the subjective causes described earlier. However, before that, appropriate measures of the magnitudes of overruns must be addressed as well as how large and prevalent overruns are in transportation sectors worldwide.

Measurement of Cost Overruns

As previously defined, cost overrun is a term often used in the context of any construction project when the actual cost does not meet/ is not meeting the budgeted/estimated cost. Its measurement is therefore the magnitude by which the actual cost is larger/smaller than the estimated/budgeted cost.

Formally and under the definitions previously given, if Y_i represents the actual cost upon project i 's completion and if F_i represents the estimated/budgeted cost for the same project, then the cost overrun for project i (CO_i) is defined as follows:

$$CO_i = Y_i - F_i. \quad (1)$$

Hence, Eq. (1) is an absolute measure of cost overruns for example, in terms of dollars. If $CO_i = 0$, then the budgeted/estimated cost was accurate; if $CO_i < 0$, then an underrun has occurred that is, the budgeted/estimated cost was greater than actual cost; and if $CO_i > 0$, an overrun has occurred because budgeted/estimated cost because the budgeted/estimated cost was less than the actual costs.

Similarly, the relative or percentage cost overrun (PCO_i), which is useful when comparing overruns across projects is defined as:

$$PCO_i = \left(\frac{Y_i - F_i}{F_i} \right) \times 100. \quad (2)$$

Note that the actual cost could be used in the denominator such that the percentage overrun is measured as a percentage of the actual cost. We, however, propose that the percentage overrun should be measured as a percentage of the estimated/forecasted/ budgeted cost, that is, how large the overrun is relative to the estimated/forecasted/budgeted cost. Our suggestions here conform to the practices in the literature of cost overruns of transportation projects, although there are a few examples where the actual cost has been used in the denominator.

Finally, when comparing the cost overruns across different groups of projects, different mean PCO , that is, ($MPCO$) measures can be used, each giving a different result as follows:

$$MPCO = \frac{1}{n} \sum_{i=1}^n PCO_i, \quad (3)$$

$$MAPCO = \frac{1}{n} \sum_{i=1}^n |PCO_i|, \quad (4)$$

$$MPCOS^2 = \frac{1}{n} \sum_{i=1}^n (PCO_i)^2, \quad (5)$$

where $MPCO$ is the mean percentage overrun, $MAPCO$ is the mean absolute percentage overrun, and $MPCO^2$ is the mean absolute overrun squared. These measures are all useful to express changes in mean (average) overruns/underruns in different ways depending on the desired result as follows. The $MPCO$ tends to be small because the negative and positive values offset each other. It is useful as an indication of whether systematic under- or overestimation occurs across a set of projects. Furthermore, it is the most

Figure 1 Different phases of planning.

commonly used measure of cost overruns in the literature. The *MAPCO*, however, assumes that all biases, irrespective of direction, are equally important to consider; hence, it uses the absolute values. Finally, because the mean *PCO* is squared, the *MPCO*² gives more weight to larger values than smaller values, but in other respects, it is similar to the *MAPCO*. Thus the *MPCO*² reflects the fact that large errors represent a much more serious problem than small errors, meaning that it is appropriate to focus primarily on larger errors to effectively reduce total errors.

Given the differences among the *MPCO*, *MAPCO*, and *MPCO*² discussed earlier, a question that still remains is which one among them is most useful to calculate/address according to different policy perspectives. The *MPCO* is most useful to consider if the policy is to infer the performance of a pool of projects as a group (or a portfolio of projects). The *MAPCO*, however, is most useful to consider if the objective is to determine the variation in performances across individual projects where overruns and underruns are assumed to be equally undesirable; it is an absolute measure. Finally, the *MPCO*² is relevant if one is specifically interested in magnifying the differences in over-/underruns between large and small projects. Some studies report all of these measures.

Another important issue that must be considered when measuring cost over-/underruns is which cost estimates to compare with actual costs at project completion. As often is the case in infrastructure planning, there are many planning phases, and different cost estimates are made in each planning phase; hence, one must be careful about estimates used to derive the magnitudes of under-/overruns. Second, it might be informative to compare estimates made at the different planning phases to obtain a measure of over-/underruns in cost estimates from one planning stage to another, assuming that the most recent estimate is more correct than prior ones. The different phases of transportation planning can generally be summarized as in [Fig. 1](#).

[Fig. 1](#) illustrates that there are different phases of planning in which cost estimates are made. Cost estimates are usually, but not always, developed throughout the different stages of project development. For example, [Cantarelli et al. \(2010\)](#) found that the cost increase from the first plans to the formal decision to build in two large Dutch rail projects was several hundred percent, but that the overruns during construction was relatively small, around 10%. Therefore, one must be careful about which estimates are being compared against each other and, importantly, compared to the actual costs; the latter comparison is the real measure of over-/underruns per the definition of over-/underruns.

[Table 1](#) explains the usefulness of measuring over-/underruns by comparing estimates made at different phases of planning against each other and against actual costs. It can be seen, for instance, that comparing an estimation made at the budget allocation phase against the actual cost is most useful as a measure of total over-/underrun as it compares the actual cost to the estimate made at the time the decision to build was made. However, comparing estimates made at the Idea Phase to those made at the National transport Plan Phase is not very meaningful. Furthermore, comparing estimates at the Idea Phase (front-end phase) to actual costs has, in the literature, been useful in the sense that it provides more information about the extent of underestimation at the front end of projects ([Welde and Odeck, 2017](#)).

The Prevalence of Cost Overruns Worldwide

Most of the literature on cost over-/underruns unanimously concludes that overruns are more prevalent than underruns. Note that this is not the same as some authors tend to conclude, for example, that overruns are always the case. We warn here that some studies have shown projects with underruns, even though the averages across samples tend to be overruns, hence the notion that overruns are more prevalent than underruns.

Next, an issue to consider when assessing the prevalence of overruns is how serious those overruns are. Normally, budgets are allocated in terms of total cost for each project. Total costs include the base cost and contingency given within a confidence interval, for example, P85 or even as plus minus x%. Thus prevalent overruns become a serious problem when overruns go beyond the confidence intervals provided at the time of budget allocations. When this occurs, projects may be stopped, leading to infrastructure users not profiting in time as promised; funds that could have been used for other profitable infrastructure and/or other sectors of the economy are out-crowded and diverted to overrun projects, and decision makers and infrastructure users alike feel deceived by those who make the estimates. These are the reasons why the prevalence of cost overruns beyond budget tolerance has caused concerns in the media and among academics worldwide.

Note that the intolerable and/or large magnitudes of cost overruns differ a great deal across countries and continents. For instance, the magnitudes of cost overruns in Norway, on average, are within tolerable limits, that is, more or less within the estimated confidence intervals ([Odeck, 2004, 2014](#)). Those studies showed that smaller projects have higher percentage overruns than larger

Table 1 The usefulness of comparing estimates made at different planning phases

Estimates at different phases of the infrastructure planning process							
		Idea Phase (front–end phase)	Impact assessment phase	National Transport Plan Phase	Action plan phase	Budget allocation phase	Project completion phase
Estimates at different phases of the infra- structure planning process	Idea Phase (front–end phase)	—	Useful for gauging how costs escalates from the Idea Phase when very little is known to the impact assessment phase when much more is known. Helps to stop a project in time.	Not very useful because reesti- mates from impact assess- ment are available.	Of little use because reestimates from impact assessment or National Transport Plan Phases are already available.	Of little use because reestimates must be conducted at the action plan level.	Useful: Estimates at the Idea Phase (front–end) are regarded to be a major catalyzer for the realization of projects. Results give insight/information that can be used in the Idea Phase of future pro- jects in estimating costs.
	Impact assess- ment phase	—	—	Very useful: Results/informa- tion can be used to revise the BCA at the National Transport Plan Phase.	Of some use: Can lead to reprioritization of projects at the action plan phase.	Useful: Results can be used to revise the BCA and, hence, lead to dif- ferent allocations and/or prioritization.	Very useful: Results on how often actual costs at the project completion phase are different as compared to estimates at the impact assessment phase can be used to revise methods of cost estimations at the impact assessment phase, which other- wise may improve the estimates of the overall socioeconomic profitability of projects.
	National Transport Plan Phase	—	—	—	Useful: Results can lead to reprioritization and changes in the action plan because actions plans are sometimes based on results from the national transport plan estimates in cases where no reestima- tions are made.	Useful: Results can lead to reallocation of funds	Useful: Indicates how prioritizations at the National Transport Plan Phase are sensi- tive to cost estimates.
	Action plan phase	—	—	—	—	Useful: Can impact budget allocations.	Useful: May indicate why one should not rely on estimates at the action plan phase and that estimates at the budget allocation phase are the most relevant to consider.
	Budget allo- cation phase	—	—	—	—	—	Very useful: The final decision to build is made at the budget allocation phase. This is the typical measure of over-/underruns in the literature.

projects. Other European countries have, however, shown larger overruns. For instance, [Lundberg et al. \(2011\)](#), in the case of Sweden, found overruns in the range 10%–20%.

We revert to why there may be differences between countries in the succeeding section, where we address how to avoid overruns.

To complete this section of the article, we provide in [Table 1](#) a summary of some studies performed worldwide since 2003 that have examined the magnitudes of cost overruns among infrastructure projects. We included both scientific papers published in journals and nonpublished reports to avoid publication biases, that is, it may be that papers are published because they give certain results, and those that do not give those results are rejected/do not get published and, hence, are unpublished. The summary results in terms of means and other measures clearly show that overruns are large worldwide, which *ceteris paribus* should lead to concern, as frequently observed by academics and the media. The weighted mean overrun (weighted by number of projects in each paper/report) across all of the studies is 40%, and the standard deviation is large. Taken together, this information supports that overruns are frequent and large, and that large variation exists worldwide ([Table 2](#)).

Concluding Remarks—Potential Ways of Avoiding Cost Overruns

We addressed the explanations of what overruns are, how they occur, the problems that they cause for decision makers, how the over-/underruns should be estimated, and how prevalent overruns of infrastructure projects are worldwide. We have attempted to be concise and not engage in typical debates between opponents of the overrun issue, such as overruns are not as large as reported, the claimed causes of overruns are not true, and the method used to assess overruns is not correct. We have instead attempted to inform, as far as possible and without being partial, as is evident in each of the section of the article.

One of the clearest conclusions that we can draw from our discussions in this article is that cost overruns remain a substantial problem for decision makers and facilities users alike and that overruns are much more prevalent than the opposite, that is, underruns. As to the causes, many different explanations exist in the literature, and there are disputes as to which ones among them are the correct explanations for the causes of overruns. A further complicating issue is that many of the explanations given are not based on empirical evidence, that is, using real observed data to prove the claim. Nonetheless, we believe that the cause of overruns is a complex mixture of the reasons that have been provided in the literature.

A final question that should be attempted to be answered in a paper such as this is how can overruns be reduced and/or what are the potential strategies for reducing them for transportation infrastructure projects? Our immediate response to this question is that the strategies depend on the explanation for the causes/prevalence of overruns that have been suggested in the literature. While building on existing literature, [Siemiatycki, \(2009\)](#) offered five approaches to control for potential overruns, to which we agree but adjust, that are as follows: (1) enhance performance monitoring throughout the construction period such that total overruns can be reduced, (2) enhance accountability and responsibility, where project managers are reminded of the consequences of overruns, (3) enhance the management capabilities of construction engineers, such as being cost conscious, and the management of complex projects, (4) apply state-of-the-art cost estimation techniques, that is, those that have been proven to work with a higher degree of precision, and (5) increase completeness and rigor of early plans, where early plans are scrutinized with respect to cost.

It should be noted, however, that the five approaches earlier are complementary and not mutually exclusive. However, it is exceedingly difficult single out any of them, as the most important empirical evidence has proven that external quality assurance of estimates is a highly effective measure, see for instance [Odeck et al. \(2015\)](#). The reasons for this are that road builders/providers have a tendency to provide estimates that are too optimistic. Quality assurance implies that the estimates made by the authorities are subjected to external scrutiny to ensure that quality standards of cost estimates are being met and to detect and correct any deviations.

Introduction

Ask a random stranger about transportation, and they will almost invariably offer a simple intuition about capacity analysis. If we knew how many cars and trucks would use a facility, then we would only need to design it to accommodate that. If more cars and trucks started to appear, causing congestion, then we could just increase capacity and the congestion will dissipate. The problem is that in most major cities, this intuition very often incorrect, and this gives rise to one of the most persistent frustrations in the transportation planning process: new roads and new lanes simply do not seem to make a dent in congestion in the long run.

As if this were not bad enough, there are even some cases where capacity has been increased but soon after, congestion not just remains but escalates. The reasons for this can be elusive, and they are often attributed to background trends of population growth, rising wealth, or perhaps even a general increase in travelers' tolerance for sitting in traffic—possibly because cars are getting more comfortable, and hands-free mobile phones help drivers make better use of driving time.

It would be comforting to think that our original intuition was correct, and that some or all of these other factors confounded the real outcome. But in fact, there is an alternate intuition that could explain this surprising response, at least in some contexts where a viable public transport alternative exists. This intuition is, essentially, that roadways and public transport respond very differently to additional use: roadways experience negative externalities in the form of congestion, while public transport experiences positive externalities in the form of improved service. Because of these externalities, improving the roadway can actually lead to a less efficient equilibrium as the natural efficiencies of public transport are undermined by the attractiveness of the road. A new equilibrium emerges that is more costly, on average, than before.

The intuition originally comes from [Downs \(1962\)](#) and came to be known alternatively as “Downs's Law of Peak-Hour Traffic Congestion” or “The Iron Law of Congestion.” Essentially the same intuition was formulated independently by [Thomson \(1972\)](#). Downs's Law is probably best known for its explanation of induced traffic, but in fact the paper of that title considers three separate cases. The third case, which [Mogridge et al. \(1987\)](#) later termed the “Downs–Thomson Paradox” (DTP), imagines that the roadway coexists with a segregated public transport alternative, as shown in [Fig. 1](#), and this turns out to be essential.

Forces Behind the Downs–Thomson Paradox

Let us be more specific about the context. Consider a dense urban area with heavy day-to-day traffic. Travelers have an alternative to driving: they can take a public transport mode that operates separately from the roadway. We can then imagine the sequence of forces that lead to the DTP shown in [Fig. 2](#), where the plus-signs and minus-signs indicate positive and negative correlations, respectively, between cause and effect.

Figure 1 The abstracted transport network.

Figure 2 Causal effects behind the Downs-Thomson Paradox.

The Fundamental Diagram

Start with the white ovals: roadway capacity (1) affects roadway attractiveness (2). This encapsulates the naïve intuition about roadway expansion, and it predicts a positive causality such that higher capacity leads to the roadway being more attractive (i.e., higher speeds). This relationship rests on some theory of congestion, of which the simplest is the so-called fundamental diagram of traffic flow. In the fundamental diagram, speeds are inversely proportional to traffic volumes and directly proportional to capacity. Holding volumes constant, only the latter relationship is important.

Induced Traffic

The naïve model may be true all else being equal, but in many cases all else is not equal. If we add the light gray ovals, we no longer have fixed traffic volume, but rather a fixed total demand (3), which splits into roadway and public transport demand. So if capacity increases and this makes the road more attractive, then some additional roadway demand (4) will emerge. The loop between (2) and (4) alternates between positive and negative, creating a balancing cyclical effect (indicated by the capital “B” in the figure). In consequence, the benefits of a capacity increase will tend to be negated. This explains how induced travel can diminish the benefits of new capacity.

Mogridge's Hypothesis

Now we add demand for public transport (5). Up to now we have not speculated on the source of the new automobile traffic demand above, but according to Mogridge's hypothesis (Mogridge and Holden, 1987), as described in Holden (1989), the dynamics of automobile demand can be explained by a corollary of Wardrop's principle. Just as Wardrop's principle proposes that drivers individually vary routes until all chosen routes have the same travel time, so too could travelers in general vary their choices of mode until either the travel times by automobile and public transport are equalized or one of them is no longer chosen at all. Mogridge (1997) later reformulated his hypothesis in terms of equalized generalized cost, rather than equalized travel time alone, thereby allowing for differences in time, comfort, and out-of-pocket costs across modes. This explains cases where an equilibrium could still be reached even if observed travel times are different between automobile and public transport.

Public Transport Attractiveness

Finally, we add the single dark gray oval, indicating the attractiveness of public transport (6). Here we make an important assumption about public transport operations: that it is a scheduled service with discrete, regular departures, and that the frequency

of these departures will be adjusted to accommodate demand. In other words, if demand for public transport increases, then the frequency of departures will increase. The shorter waiting times improve the attractiveness of the service, leading to yet more demand. This phenomenon, known as the “Mohring Effect” (see Chapter 49, Mohring Effect), is central to the scale economies argued in Mohring’s (1972) classical model, and it forms an essential component of Downs’s (1962) original argument. Later variants have supposed that rather than change departure headways, per-trip fares might instead be reduced. In either case, public transport usage is assumed to have positive externalities on the service characteristics; this leads to a reinforcing cyclical effect (indicated by the capital “R” in the figure).

The Shifting Equilibrium

Sure, all the forces in Fig. 2 may exist, but what about this combination leads to an outcome where an improvement in the road worsens the situation for everyone? We can illustrate the forces above diagrammatically, as done by Mogridge (1997). In Fig. 3, the cost curves for auto and for public transport are plotted against the share of demand that chooses each option. Moving rightward along the horizontal axis, more travelers choose to travel by automobile; moving leftward, more take public transport.

There are two cost curves for auto, one before and one after improving the road, and one cost curve for public transport. Crucial to the Downs–Thomson Paradox are the principles that automobile costs increase with its mode share, while public transport costs decrease with its mode share and therefore increasing with auto mode share; hence all three curves are upward-sloping.

The two auto cost curves depict an improvement in the roadway, leading to lower costs for the same demand by automobile. This moves the equilibrium point from A to B. Were there only a fixed auto demand, this would certainly lead to a reduction in costs. But since in this case demand can choose between auto and public transport, we can see how the improvement leads to a higher auto demand, to the extent that the new average costs by auto are actually higher than before. Moreover, the remaining public transport passengers also see higher costs due to fewer riders. In other words, both modes are more costly than before.

A Numerical Example

A final illustration uses a numerical example to demonstrate how different road capacity levels could lead to different outcomes for both modes. Fig. 4 records the travel time and demand levels over varying levels of roadway design capacity. Similar illustrations can be found in earlier explanations such as Fig. 3 in Kitamura et al. (1999), Fig. 1 in Abraham and Hunt (2001), and Fig. 5 in Afimeimounga et al. (2005).

In this example, travelers have identical preferences, among which that they value travel time on either mode the same, and that is the only consideration. In other words, this model incorporates Mogridge’s hypothesis that when both modes are chosen, travel times must be equal between them. To give precision to the cost curves, the example employs a simple power-based curve to represent roadway congestion, whereby delay time is related to a ratio between demand and the road’s nominal capacity; and for public transport it assumes that vehicle headways are determined by demand. If travelers shift from public transport to automobile, then road congestion will increase while the public transport vehicles come less frequently, leading to longer average wait times.

Moving from left to right, we start with very low roadway capacity, so for the two modes to have equal travel times, only a very few travelers will drive. As roadway capacity increases, it draws more demand from public transport, to the point that travel times increase. This continues up to the point (in this case, a roadway capacity of somewhere between 600 and 650 travelers per hour) where public transport can no longer supply a service that is competitive with the automobile in travel time terms. Increasing

Figure 3 Diagrammatic explanation of the Downs–Thomson Paradox. Source: Based on Mogridge, M.J., 1997. The self-defeating nature of urban road capacity policy: a review of theories, disputes and available evidence. *Transp. Policy* 4, 5–23. [https://doi.org/10.1016/S0967-070X\(96\)00030-3](https://doi.org/10.1016/S0967-070X(96)00030-3).

Figure 4 Numerical illustration of the Down–Thomson Paradox.

headways lead to increasing average public transport travel times that are higher than auto travel times, so no one chooses public transport any longer. At this point, there is a discontinuity in travel times: travel time for public transport is no longer relevant; and for the automobile, travel times jump as the last public transport travelers jump into their cars and there is no longer an equilibrium between modes. For the remaining road capacity levels, all 1000 travelers choose the automobile and the only question is how much congestion they endure as nominal capacity approaches 1000.

Evidence of the Downs–Thomson Paradox

The counterintuitive result of the Downs–Thomson Paradox is provocative, emphasizing the importance of viewing it in light of evidence. Unfortunately, an empirical confirmation or rejection of the DTP using real-world field data has so far eluded researchers. It is simply too difficult to isolate the relationship between roadway expansion and a deterioration in congestion. In the dense urban areas where the DTP is meant to apply, population growth, economic development, and other infrastructure changes will almost certainly confound any observations.

Instead, the evidence for the overall DTP effect has mostly come from analytical approaches, as well as a few experiments in laboratory environments. The basic analytical case was already set out in simple terms by [Mogridge et al. \(1987\)](#). [Abraham and Hunt \(2001\)](#) reformulated the problem in a discrete mode choice model, allowing some observations on when the paradox does and does not arise. [Kitamura et al. \(1999\)](#), using a cellular automata-based model, was able to reproduce the DTP, and [Afimeimounga et al. \(2005\)](#) did the same using a queuing model.

Laboratory Experiments

A few experiments in simulated settings have confirmed the DTP under controlled conditions. [Denant-Boemont and Hammiche \(2009\)](#) applied a game-theoretic approach and conducted a laboratory experiment with simulated setting, finding evidence of the DTP when increasing roadway capacity, but not when decreasing it. [Dechenaux et al. \(2014\)](#) examine two new facets: alternative pricing policies for the metro; and population size. Use game experiments. Confirm DTP for increasing capacity. Also, average cost pricing for the metro reduces road congestion.

Component Effects

In addition to the overall effect of counterproductive roadway expansion, each of the individual relationships in [Fig. 2](#) could also be tested. Some are uncontroversial: it is well understood that congestion can increase from either a reduction in capacity for fixed demand (1→2) or an increase in demand for fixed capacity (4→2), and the demand scaling relationships with modes (3→4 and 3→4) are straightforward. More interesting to examine are the following:

- Cross-elasticities of demand between public transport and roadways (6→4, 2→5)
- Induced travel demand on roadways and public transport (2→4 and 6→5)
- Positive externalities in public transport (5→6)

Cross-Elasticities

The closest efforts to examine the DTP using field-collected data appear to have probably been by [Mogridge \(1997, 1990\)](#), who examined records of highway and public transport expansion in the London Region along with historical measurements for operating speeds on both modes. The key findings were that despite substantial increases in roadway capacity over the studied time period, average speeds by both automobile and public transport steadily declined. According to [Mogridge \(1997\)](#), the parallel decline in speeds for the two modes supports the DTP, at least to the extent that there is an equilibrium process between the two modes that incorporates cross-elasticities of demand. Indeed, taking a generalized cost view, it is not actually necessary for travel times to be the same for an equilibrium process to exist, but rather it is sufficient that generalized costs are the same. However, as with most such time series data, the data do not support a robust examination of the causal relationship between capacity changes and travel speeds, since confounding factors such as population and wealth cannot easily be controlled for.

Another empirical analysis comparing mode choice to the relative travel times between auto and public transport ([Nss et al., 2001](#)) found a strong relationship. Still, this is only partial evidence of the DTP, supporting at least the notion that mode choice is subject to cross-elasticities, but it does not confirm the causal effect of capacity changes on travel times for either mode. A broader discussion of cross-elasticities can be found in Chapter 36, Cross-Elasticities Between Modes.

Induced Travel

A large literature exists on the drivers of travel demand (see Chapter 21, Demand for Passenger Transport) due to capacity increases, especially on roadways. Among these, it is notable that [Noland \(2001\)](#) made specific reference to the Downs–Thomson Paradox in setting the context for his findings. While Noland found strong evidence of induced demand in terms of vehicle-miles traveled, no results were given on whether travel time savings from the capacity increase were partially or fully offset by this induced demand. In sum, it appears that no real-world evidence so far fully confirms the Downs–Thomson Paradox.

Positive Externalities in Public Transport

An extensive literature exists on scale-economies of public transport, which extend far beyond the Mohring effect and indicate potential for both increasing and decreasing costs. Chapter 49, Mohring Effect presents a thorough discussion.

Do the Downs–Thomson Conditions Really Apply?

If the Downs–Thomson Paradox can only be confirmed in analytical studies, simulations, and laboratory experiments—all of which require some strong assumptions about the urban geography, the public transport operator, and prices—then it is worth asking whether these assumptions are realistic for real-world conditions, and what the limits are for the DTP to arise.

[Basso and Jara-Díaz \(2012\)](#) incorporated prices for both public transport and the roadway, finding that the scenario where the operator minimizes costs is not the same as the optimal scenario in socio-economic terms. [Bell and Wichensin \(2012\)](#) found that the DTP would not occur if a profit-maximizing operator does not pass the positive externalities of increased demand on to passengers. [Zhang et al. \(2014\)](#), when examining a variety of situations including different operator objectives and instruments, came to the same conclusion, but also showed that if the operator maximizes social utility, subject breakeven conditions, then the DTP does occur.

[Abraham and Hunt \(2001\)](#) also considered multiple operating policies, but with both tested policies (constant load-factor and minimum-cost), they found that the DTP would be most prominent when the transit market share is low. This contradicts the argument by [Mogridge et al. \(1987\)](#) and [Holden \(1989\)](#) that the DTP is most likely in areas with heavy transit usage.

Conclusions

The Downs–Thomson Paradox is provocative, but unfortunately there have never been any firmly confirmed sightings in the field. Moreover, the conditions of the Downs–Thomson Paradox are strict. That said, even if the required conditions are not always be present, they are certainly common enough in modern cities. Given the right conditions, the paradox has been shown to emerge in simulations, in laboratory experiments, and by analytical methods. This should be enough to give transportation planners pause: it simply cannot be assumed that a roadway expansion will lead to reduced congestion, or even that congestion will be the same after expansion. A careful examination is needed of the interaction between different transport modes and their relative economies-of-scale. Without this, there is a reasonable risk that scarce public resources are spent on infrastructure with no real social benefit.

Introduction

During the 21st United Nations Climate Change Conference in Paris, it was agreed that countries must collectively reduce long-term greenhouse gas (GHG) emissions to a level which ensures that the average global temperature increase remains below 1.5°C. Most sectors are already significantly reducing their GHG emissions, with the transportation sector being a major exception. Furthermore, the projected increase in the global car fleet over the coming decades—mainly driven by economic development in developing countries—makes a reversion of this increasing trend in GHG emissions challenging, or even impossible, if no significant changes in mode choice or technical improvements occur. Hence, the current trajectory of transport sector emissions is not congruent with international emission reduction agreements.

In light of this, plug-in electric vehicles (PEVs) are one promising technology that can play a pivotal role in reducing transport emissions. PEVs are already at a high level of technological maturity and their usage does not require significant behavioral changes from consumers, especially compared to nonmotorized transport options. Other arguments for nations to strive for electrified transport system include: lowering dependency on (foreign) fossil fuels, and strengthening local industry.

In this chapter, PEVs include both battery electric vehicles (BEVs) and plug-in hybrid electric vehicles (PHEVs), given these vehicles can be plugged-in directly to charge using electricity, and therefore take advantage of the cost and environmental benefits of switching to this alternative transport energy source.

Today, emissions from transport are highly correlated with economic development. Besides this income-effect, usage patterns of traffic participants do not change significantly over time. Consequently, significant behavioral changes in terms of substantial mode shifts in the short-term seem unrealistic. Conversely, PEVs, together with the uptake of renewable energy, demonstrate a convincing opportunity to reduce GHG emissions from future transport systems.

Although PEVs' level of technological maturity is high, and their total cost of ownership is already comparable to conventional fossil fuel vehicles in many jurisdictions, most potential users do not adopt this new technology largely due to a lack of supply (mainly few models and insufficient consultation at the point of sale), high upfront investment costs, and other systemic failures, such as limited public charging infrastructure. From an economic point of view, these perceived barriers, together with the fact that not all future costs from fossil fuel vehicles are sufficiently internalized in the cost functions of decision makers, indicates a market failure, which requires market intervention by the state.

Correspondingly, many governments already support the market uptake of PEVs by various policy instruments in order to increase overall welfare. The success of these different policy instruments relies on several factors, and no unique recommendation or tendency toward a single superior instrument can be given, yet. Nevertheless, the choice of the right instrument, or set of instruments, determines the government's investments: choosing an ineffective policy instrument can quickly lead to a significant misallocation of tax revenue. Therefore, the selection of the right policy instrument is decisive. This chapter aims to shed light on current insights into this new market, and in doing so, help to inform these strategic decisions.

Plug-In Electric Vehicle Policy Examples

Policy instruments designed to support the uptake of plug-in electric vehicles come in many shapes and forms. The following section of this chapter includes a number of contemporary examples from some of the leading, early adopting PEV markets.

China is the largest global automotive market and has had, and continues to have, a huge impact on global PEV developments. Chinese PEV policy instruments have combined strong financial incentives with a quota system, supported by nonfinancial incentives and local policies. Exemptions from taxes account for price decreases in the order of EUR 5,000 to EUR 8,500. Large Chinese cities, such as Beijing, Shanghai, or Shenzhen, also provided waivers from license plate availability restrictions. Traditionally, Chinese Government plans and targets have followed a five-year cycle, which provides a certain planning period for both consumers and industry. In the next phase, the Government plans to progressively reduce the magnitude of financial incentives and transition to a quota scheme for “New Energy Vehicles”—the term applied to PEVs in China. In that system, every manufacturer participating in the Chinese market has to comply with a predefined share of PEVs. The credits awarded through this scheme vary according to vehicle type and driving range: longer range vehicles receive more credits, and as such, BEVs receive more credits than PHEVs.

Germany, with a strong automotive industry, has had a long-term R&D industry support scheme for PEV technology. In recent years, this has been coupled with rebates and tax reductions to boost PEV sales. Additionally, local support, such as access to bus lanes or the support of strategic municipal planning, has also been available. As part of the EU, German car manufacturers are also subjected to mandates to reduce tailpipe CO₂ emissions from their vehicles sold. So far, under these provisions, PEVs have continued to receive extra credits.

Norway, which has set a target of banning fossil fuel vehicles sales by 2030, started supporting PEVs already in the 1990s by exempting them from the nation’s relatively high vehicle registration taxes. The vehicle tax exemptions amounted to around EUR 10,000 per vehicle, making PEVs cheaper to purchase than their fossil fuel counterparts, in addition to already being cheaper to operate. These financial incentives, coupled with a large number of waivers on fees, such as road tolls and ferries, provide a highly favorable environment for PEV uptake, and for BEVs in particular. This has led to Norway being the leading PEV market globally, with a new vehicle sales share of 46% in 2018. BEV taxation is planned to remain unchanged for more years, while PHEV incentives could change. Furthermore, a comprehensive network of fast charging stations has been built to facilitate long-distance trips in Norway. At a local level, the city of Oslo is also banning fossil fuel vehicles from the city by allowing parking only for PEVs. Overall, the strong incentives and support for PEVs are in line with Norway’s national target to have zero sales of fossil fuel vehicles by 2025.

Another approach that emphasizes long-term planning and creates more of a technology push are quotas, or zero-emission vehicle (ZEV) mandates, in which PEVs are included. National or regional governments, such as California in the United States or British Columbia in Canada, set long-term targets for the sales shares of ZEVs to be met by automakers. In California, the ZEV mandate seems to have accelerated industry investment in ZEV technology. California is today one of the leading PEV markets and represents approximately half of total PEV sales in the United States.

Categorization of PEV Policy Instruments

“Policies” in general describe a plan of action adopted by a specific actor to support a goal, while “public policy” refers to a plan of action that is taken by government. Policies involve strategies, instruments, and the policy process. The focus of this chapter is specifically on the policy instruments. We focus primarily on national policies as these have received the most attention, but super-national, regional, or city-level policy instruments can be important levers too.

There is a growing body of literature analyzing and defining policy instruments for sustainability transitions in general, but also for PEVs in particular. Policy instruments for the present chapter are defined as concrete tools to achieve overarching policy objectives, and in most cases, to address specific market barriers. In the case of PEVs, the three principal market barriers are:

1. **Lack of market supply:** Although PEV technology is now relatively mature, given there are significant changes required in vehicle manufacturing, particularly in regards to supply chains, many incumbent manufacturers are still repositioning their businesses to be capable of expanding the supply of PEVs to the market. A lack of supply leads to a lack of choice, particularly across vehicle classes.
2. **Higher upfront costs:** During the early stages of market development—as with most new technologies—PEVs cost more to purchase. Although PEVs are much cheaper to operate, the market has still not reached purchase price parity with fossil fuel vehicles. The higher purchase price leads to a reduced demand from potential buyers.
3. **Systemic failures:** Given the transition to PEV technology inherently requires system-wide changes, there are many existing gaps, or systemic failures, slowing the uptake of PEVs. This includes a perceived lack of charging infrastructure, leading to consumers experiencing range restrictions or anxiety, a general lack of understanding of the technology, resistance from incumbents like vehicles dealers due to uncertainty about the future, as well as a lack of standardization across suppliers. While in many developed countries we are already seeing sufficient charging infrastructure from a theoretical perspective, the perceived uncertainty is still dominating consumer opinion.

There are many different PEV policy instruments available to address these principle barriers, and many different categorizations for these instruments. Typically, authors distinguish between (1) economic or regulatory instruments, (2) between sticks, carrots, or sermons, (3) between market pull or technology push, or further much more granular distinctions. All of these distinctions capture some important aspect of the policy instrument. However, here we follow the literature of policy mixes in sustainability transitions,

Table 1 An example of PEV policy instrument categorization including examples of policy instruments

<i>Policy categorization</i>		<i>Primary purpose</i>		
		<i>Technology push</i>	<i>Demand pull</i>	<i>Systemic</i>
Primary type	Economic instruments	R&D grants; contestable funds	Purchase subsidy; income tax credit; sales tax; registration fee; annual vehicle tax; toll road fee; parking fee; emissions tax; fuel tax	Charging infrastructure subsidies; cooperative R&D grants; broader transport tax reforms
	Regulatory instruments	CO ₂ emissions standards; quotas; targets; city planning measures	Ban of fossil fuel vehicle sales; free bus/transit lane access; free public charging	Emissions zones; standardization
	Information	Vehicle dealer education	Labeling; awareness campaigns; test drive events; public exhibitions; public event integration; tourism programs	Stakeholder and public dialogues

which is well-applicable as PEVs are a sustainable transportation technology, and their introduction implies a transition for many aspects of the automotive regime, and society in general.

Given the breadth and variety of policy instruments available, and following the literature on policy mixes in sustainability transitions, the remainder of this section categorizes policy instruments based on their primary purpose and primary type; with both categories explained further below.

Primary Purpose

Categorization of policy instruments by primary purpose principally relates to the main intended outcome of the instrument. It should be emphasized that instruments can have more than one purpose, but typically the main or primary purpose is clear, particularly in regards to the specific market barrier for which the policy instrument aims to address, for example, lack of supply, high upfront costs, or systemic failures. PEV policy instruments can be categorized into the following three primary purposes:

1. **Technology push or supply side** instruments foster the development and market formation of PEVs. For example, low-carbon fuel standards; PEV quota systems.
2. **Market pull policy instrument** create or stimulate demand for PEVs. For example, purchase rebates; registration fee discounts.
3. **Systemic policies** help to improve the general systemic attributes for PEVs. For example, provision of public charging infrastructure; introduction of emissions zones; technology standardization.

Primary Type

In addition to primary purpose, PEV policy instruments can also be categorized by their primary type. The three primary types of PEV policies are:

1. **Economic instruments** directly influence the total cost of ownership of PEVs. For example, purchase price rebates, registration fee discounts, annual tax reductions.
2. **Regulatory instruments** improve market conditions in favor of PEVs, compared to incumbent alternatives, through technical specifications. For example: PEV quotas, fuel standards, fossil fuel vehicle bans, low emission zones.
3. **Information** improves awareness of the technology in the society. For example, labeling at the point of sale, public information campaigns, test drive events, public exhibitions.

Overview of Policies

By combining primary purpose and primary type, it is possible to categorize PEV policy instruments into nine distinct categories, as shown in [Table 1](#).

[Table 2](#) includes further details on each of the example PEV policy instruments categorized in [Table 1](#), including regional examples of where these instruments have currently (2019) been implemented around the world.

While there is some evidence to suggest that specific policy instruments appear to have a greater impact on PEV diffusion compared to alternative instruments, it is increasingly becoming clear that there is no “silver bullet” for encouraging the uptake of PEVs. This is in line with arguments provided by the policy mix literature, which concludes that an effective transition policy needs instruments to be in line with an overarching strategy, that is, perceived by market actors to be reliable. Furthermore, the specific design features of instruments play a role, for example, rebates lead to differential impacts, if they are provided upfront compared to if consumers need to claim money back at a later stage.

Table 2 Example list of PEV policy instruments

<i>Example PEV policy instruments</i>	<i>Primary type</i>	<i>Primary purpose</i>	<i>Description</i>	<i>Regional examples</i>
R&D grants, contestable funds	Economic instruments	Technology push	Funds established to support R&D into PEV technology, and support trials of PEV technologies, as well as use cases that would be beneficial but are not yet commercially viable.	New Zealand, Australia, Germany
Purchase subsidy		Demand pull	A point-of-sale subsidy that reduces the upfront cost of purchasing a PEV.	British Columbia (Canada)
Income tax credit			A credit that can be used to offset or reduce income tax liability, indirectly reducing the upfront cost of purchasing a PEV	US
Sales tax discount			A reduction in sales tax for PEVs.	US, Norway
Annual registration fee discount			A reduction in annual registration fees for PEVs	Germany, France
Toll road or congestion tax discount			A reduction in toll road/congestion charges for PEVs	Norway, London
Parking fee discount		Systemic	A reduction in parking fees for PEVs	Oslo, Germany
Company car tax discount			A reduction in company car tax for PEVs	Norway, Netherlands, Sweden
Emissions tax			A road or vehicle tax based on emissions rates, favoring PEVs with low or zero emissions.	Several EU countries
Fuel tax			A tax to increase the cost of using fossil fuels.	Several EU countries
Charging infrastructure			Provision of charging infrastructure to address PEV range anxiety, and bolster market confidence.	Australia, EU, Japan, US
CO2 emissions standards	Regulatory instruments	Technology push	Standards to progressively reduce CO ₂ emissions of the fleet.	US, EU, Japan
Targets or quotas			Targets or quotas used to stimulate market supply of PEVs.	Norway, New Zealand, UK, US
City planning measures			Measures to normalize the integration of PEVs into planning, including mandating charging infrastructure requirements for buildings, car parks, etc.	EU, UK, US, Australia
Ban on fossil fuel vehicle sales		Demand Pull	Bans to send a clear signal to consumers and industry about the PEV transition timeline.	France, UK, Norway, Netherlands, China
Free bus or transit lane access			Regulation that provides PEV owners with the added benefit of bus/transit lane access.	Oslo, California, UK
Free public charging			Regulation that provides PEV owners with the added benefit of free public charging.	Oslo
Emission zones			Zones restricted to low and/or zero emissions vehicles to encourage a transition to these vehicles.	Germany, UK
Standardization		Systemic	Implementation of technical standards to ensure consistency across suppliers and simplify experience for PEV users.	EU, US, Japan
Vehicle dealer education	Information	Technology push	Awareness campaigns to educate vehicle dealers on PEV technology and minimize dissemination of misleading information	US
Labeling		Demand pull	Use of labels to promote awareness of PEV benefits compared to other technologies. Also use in addition to, or as part of vehicle number plates to promote awareness in addition to facilitating regulation of PEV benefits, such as access to bus or transit lanes, PEV-exclusive parking, etc.	Norway, US
Awareness campaigns			Campaigns to improve public awareness and understanding of PEV technology.	British Columbia, Norway, US
Test drive events			Specific events held to provide the general public with opportunity to experience PEV technology, and address any questions, including potential concerns.	US
Public exhibitions			Public exhibitions to demonstrate PEV technology.	US
Public event integration		Systemic	Integration of PEV technology with public events to raise profile and general awareness.	London Olympics, Beijing Olympics
Tourism programs			Strategies to encourage EV tourism, with the ambition of address PEV technology misconceptions through real-world experiences and influence consumer preferences.	Oregon, Germany
Stakeholder and public dialogues			Increase profile and awareness of PEV technology.	Norway

This is underlined by the fact that leading PEV markets, such as Norway, have implemented a range of policy instruments spanning across the primary type and primary purpose categories outlined here, in addition to a long-term policy goal, that is, the ban of fossil fuel vehicles. This makes sense, given there are several barriers to PEV diffusion—as mentioned above—that each require differing approaches in order to be resolved.

For example, while the higher upfront investment costs of PEVs are a significant barrier to uptake that can be partly addressed through demand pull, economic instruments, such as purchase rebates, or vehicle tax discounts, these instruments will not address the PEV market barrier of a lack of charging infrastructure (a systemic failure). To address this barrier, a systemic, economic instrument, for example, a charging infrastructure subsidy to increase charging opportunities, could be combined with demand pull, information in the form of public awareness campaigns to address misconceptions about PEVs' limited driving range capabilities. Again, however, these instruments are much more powerful, if market actors perceive them as being part of a longer-term strategy that is consistently followed.

Policy-makers must also take into account regional considerations and identify a package of policy instruments that make sense for the local market, while addressing the principal barriers to PEV diffusion. For example: there is some evidence to suggest that part of the monetary benefit of vehicle purchase subsidies is captured by vehicle manufacturers—as is the case with most government subsidies. While this may make sense in regions that manufacture PEVs, such as Germany, UK, US, Japan, and China, where governments already support the local vehicle manufacturing industry, in non PEV-manufacturing nations, such as Norway, Denmark, Ireland, Australia, and New Zealand, directly subsidizing foreign manufacturers makes less sense. Instead, the same pool of available funding could potentially be more effectively used through other demand pull, economic instruments, such as vehicle tax reductions.

Discussion and Conclusions

There are a significant number of policies that decision makers can choose from to support the market diffusion of PEVs. Choosing the right policy instrument, and its adequate design, as well as the appropriate policy combination, depends on context, market conditions, as well as the national transition pathway. The evidence so far on demand pull, economic instruments, such as purchase subsidies, suggests that they foster PEV market diffusion, even if the effect is rather low. Yet, when the purchase price of PEV and conventional fossil fuel vehicles is similar due to high incentives, and as part of a broader strategy, the market can quickly tip in favor of PEVs, as has been the case in Norway.

There are differences in responses to the instruments, for example, a point of sales rebate seems to be more efficient than income tax deductions, however, more studies are needed to better discern the differences in effects. On the supply side, most research has been on the California ZEV mandate. Studies find that the mandate has had a positive impact on innovation activity for OEMs, increasing research and development.

Many of the leading PEV markets, such as Norway, have implemented several instruments to support the diffusion of PEVs. When designing a policy mix, market acceptance becomes an important factor for success to ensure market actors on the demand and supply side invest in the desired way. To increase acceptance, policy making and implementation should be coherent, and the policy mix should also be consistent. For example, when planning for a ZEV mandate it is important to understand how it interacts with other policies regulations to avoid duplications and conflicting policy mechanisms.

It is also important to keep in mind that the empirical evidence so far on the efficiency and effect of policy instruments for PEVs is caveated by the fact that most markets, with the possible exception of Norway, are still in the early phases of market diffusion, and thus the results might change as markets continue to develop. Given this, policies will need to be adjusted as markets continue to develop. Evidence from California shows that the number of “free-riders” for incentives (i.e., the number of people that would have purchased an PEV even without incentives) has decreased as the market has expanded. In Norway, as the number of PEVs on the roads have increased, local regulations, such as access to bus-lanes, have been phased out while uptake continues to grow. This has also been, in part, due to the unintended negative consequences of increased congestion from higher volumes of PEVs using these road facilities, highlighting the importance of these measures being temporary in duration, and closely monitored in order minimize negative effects.

In the case of Norway, the financial cost of PEV incentives has been high, with the benefits flowing largely to higher-income Norwegian households. In saying this, it must be recognized that almost all new technology is initially expensive, and only becomes affordable for the mainstream through economies-of-scale. The Mercedes-Benz S-Class was the first production vehicle to have an anti-lock braking system (ABS) in 1978, which retailed for 150,000 EUR/\$US 170,000 (in 2019 currency). The only reason these systems are now in vehicles retailed for under 10,000 EUR/\$US 11,000 is due to economies-of-scale. The same concept applies to PEVs, with many of these vehicles over 35,000 EUR/\$US 40,000 already approaching price parity with conventional fossil fuel vehicle equivalents. These upfront price reductions have been accelerated by policy instruments, which have led to increased consumer demand, and driven economies-of-scale across the entire PEV supply chain.

It is also important to understand the financial costs and impacts of different policy instruments, and weigh these up against the expected co-benefits of implementation, for example, lower emissions, reduced transport costs, improved air quality, etc. It is sometimes argued that other measures, such as nonmotorized (or active) modes are more cost-efficient mechanisms for emissions reductions in the transport sector, but this would require significant changes in current mobility preferences, which appears unlikely in the current market. Others argue that emissions reduction in other sectors is more cost-efficient (in terms of CO₂ abatement costs),

for example, in electricity generation, and that the electrification of road transport is a rather slow emission reduction mechanism due to required changes in vehicle production facilities and supply chains, in addition to behavioral inertia and a lack of charging infrastructure, among other factors. This is principally why strong policy support is required now to assist in accelerating the transition to electric vehicles (in conjunction with economies-of-scale leading to upfront cost reductions), in parallel to efforts being made in other sectors, to ensure that global emission reduction targets can be met as quickly as possible. Without the electrification of road transport, the rapidly increasing global car stock will lead to further increases in emissions.

As battery costs decline further, PEVs are expected to become cost-competitive with conventional fossil fuel vehicles, and thus, purchasing incentives may no longer be required. It is, however, critically important that any phase out of policy instruments is done gradually, and is clearly communicated to consumers, to avoid market shock. Even if PEV prices fall, and supply increases, there may still be rationale for continued policy support, if other systemic failures remain, including ongoing range anxiety due to a lack of charging infrastructure and low consumer awareness. As such, consumer education campaigns, and other systemic policy instruments, will continue to be important. The private sector will also play an increasingly important role in the rollout of PEV charging infrastructure, with this investment being catalyzed through initial government support and clear standards, as part of a broader PEV strategy.

A further issue that has not been addressed in this chapter is the phasing out of the incumbent fossil fuel vehicle industry. There is an additional need to support the development of industry transition strategies that consider the socioeconomic effects of these changes, particularly in regions that are currently economically-dependent on fossil fuel vehicle production, and/or the associated maintenance requirements of conventional drivetrains. If these broader impacts are not taken into account, and actively planned for by policy-makers, incumbent fossil fuel vehicle businesses, and those who they employ, may try to resist the diffusion of PEV technology, which would not only have dire environmental consequences, but could also have long-term negative economic ramifications for the regions concerned, if they are left behind in this global transition.

Biographies

Dr. Jake Whitehead is the Founder and Secretariat of the Australia and New Zealand Clean Transport Coalition, a member of the International Electric Vehicle Policy Council, and holds two PhDs in Transport Science and Engineering. Dr Whitehead's research primarily focuses on the costs, benefits, opportunities, and risks of clean transport technologies, as well as understanding the impacts of government policies on supporting and managing the uptake of these innovations. Dr Whitehead has also undertaken research on the synergies between clean transport and energy systems, in particular through the rollout of electric vehicle-to-grid systems, as well as the effectiveness of different transport technology pathways on reaching global emission reduction targets. Dr Whitehead has worked closely with governments and businesses internationally to advise on sustainable transport policies. These efforts have included co-coordinating the development of Australia's most comprehensive electric vehicle strategy for Queensland.

Dr. Patrick Plötz studied Physics in Greifswald, St. Petersburg and Göttingen. Dissertation in Theoretical Physics on correlated electrons in one-dimensional systems. Additional studies of Philosophy and History of Science in Göttingen. Doctorate degree in Theoretical Physics from the University of Heidelberg (Institute for Theoretical Physics) on complex dynamics in cold atomic gases. From January to December 2011 researcher in the Competence Center Energy Policy and Energy Systems at the Fraunhofer Institute for Systems and Innovation Research ISI, since January 2012 in the Competence Center Energy Technology and Energy Systems.

Dr. Patrick Jochem is a post-doc at the Karlsruhe Institute of Technology (KIT) and Associate Editor of Transportation Research Part D: Transport and Environment. Since 2009 he is leading the interdisciplinary research group “Transport and Energy” at the Chair of Energy Economics and since 2012 the eMobility Lab at the Karlsruhe Service Research Institute (KSRI). He is author of more than 100 scientific peer-reviewed papers and has a strong funding record. In 2009, he received his PhD in transport economics, which was funded by the German Federal Environmental Foundation (DBU). In 2014, he was awarded by the Heidelberg Academy of Sciences and Humanities. He studied economics at the universities of Bayreuth, Mannheim and Heidelberg. His research interests are in the fields of electric mobility, energy system analysis, and ecological economics.

Frances Sprei is an Associate Professor in Sustainable Mobility. She has a PhD in Energy and Environment from Chalmers University of Technology in Sweden. Her research assess different mobility services such as electric vehicles, car-sharing, and autonomous vehicles and studies their adoption and diffusion. Her methods are interdisciplinary and she takes into consideration technical, economical, and behavioral aspects.

Dr. Elisabeth Dütschke studied psychology, business administration, and marketing at TU Darmstadt and RWTH Aachen. For her PhD thesis in organizational behavior at the university of Constance she received an award from Südwest Metall as an outstanding contribution to research. Further work experience includes consulting of private and public organizations and journalism as well as university lectures. Since June 2009 at the Fraunhofer ISI as senior scientist and project leader she has been involved in a large number of national and international research projects. Since March 2019 coordinator of the Unit “Actors and Social Acceptance in the Transition of the Energy System.” Her work focuses on the human perspective on a changing energy system. She is the main contact for societal issues around the energy transition for the institute.

Introduction

One of the most significant results in the rail sector during the last quarter of the 20th century was the enormous decline in transport market share at the worldwide level, and mainly at the European level. In particular, a drastic fall in rail modal shares was produced both in the passenger and freight markets in Europe in the 1970s and 1980s. For the EU15 countries, the modal share for rail passenger transport fell from 10.4% in 1970 to 6.7% in 1990. The decline was even more considerable for freight with rail decreasing from 21.2% modal share in 1970 to 11.1% in 1990 (OECD, 2013).

Furthermore, this decline provoked a real deterioration in the financial accounts of many of railway networks around the world. One of the first replies to this situation was the redefinition of the traditional management system in railways. This system had consisted in public ownership and management of both infrastructure and all rail operations by a single firm. Therefore, complete integration (through the vertical dimension between infrastructure and rail operations and the horizontal level between all the different rail services) was the main economic feature of railway systems.

The first step in the restructuring of the rail industry in Europe was the Directive 91/440, which promoted the separation of accounting systems for rail operations and infrastructure. Additionally, this Directive stimulated a rail management for the industry, which was more independent of the State. The second step in this restructuring process was the launch in 1996 of the *White Paper* (known as the First Railway Package), with the objectives to favor the opening of the market, the improvement of the financial accounts and boosting market forces and an effective competition in the rail market. The subsequent Railway Packages tried to foster and create an integrated European rail area at both the legal and technical levels and at the same time to open international passenger and freight transport to competition in the European Union. Lastly, the Fourth Railway Package introduced the principle of competitive tendering for public service contracts and promoted the opening of the market for domestic passenger transport services by rail.

Our paper will be classified into three parts. Firstly a description of the different restructuring measures in the European rail industry will be presented. We differentiate between measures at vertical dimension, that is, on the degree of separation between infrastructure and rail operations, and measures at horizontal dimension, that is, those measures directed to promote competition in rail operations. Secondly, the different approaches and methodologies used to evaluate the effectiveness of these measures will be presented and described. Thirdly the evaluation of the effects of these reforms will be discussed, describing the different results obtained by the literature. Finally, we conclude with some remarks and policy recommendations.

The Restructuring Process in the European Rail Industry

Restructuring Measures at Vertical Dimension

As previously mentioned, one of the first goals of the EU in the rail markets was to promote the separation between infrastructure and rail operations. Separation implied unbundling those rail competitive activities (like rail operations) from those activities that have the features of natural monopoly. There are very detailed papers where the *pros* and *cons* of separating infrastructure and rail operations are described in depth in a detailed way. The main advantage of vertical separation was that it would allow greater competition in the rail sector. Abbott and Cohen (2017) describe that additionally vertical separation will:

- Create incentives to reduce costs and promote innovation from increased competitive pressures amongst train operators.
- Lead to greater specialization of operators and their expansion into other markets.

- Create competitive neutrality between train operators.
- Create a greater degree of transparency for policymakers in the form of information on access pricing, track usage, etc.

However, there is some evidence that scope economies can be lost in a structure which separates infrastructure and rail operations. There are some examples where coordination between infrastructure and operations can lead to deterioration. So, maintaining or upgrading the rail track and other facilities directly affects operating scheduled services and vice versa. This occurs due to the existence of a technological interdependence between infrastructure and vehicle technologies (Pittman, 2005). For this reason, a track infrastructure owner could be reluctant to bear the risks of specialized investments without long term contracts for a specific user.

Summarizing, the potential gains obtained from a separated structure in terms of greater competition should outweigh the loss of coordination and scope economies of an integrated structure. Thus, the separation degree can be implemented at different levels:

- Only at an accounting level: requiring that different accounts must be prepared for infrastructure and rail operations, but within the same entity.
- Organizational level (or “holding model”), where rail operations and infrastructure are managed by different subsidiaries within one holding company and taking independent decisions.
- Institutional separation, where rail operations and infrastructure are managed and organized by different and totally independent companies.

While some European countries have kept an integrated rail structure (such as Ireland, Hungary, Lithuania, Luxembourg, or Russia), most European countries have opted for a more disintegrated structure (United Kingdom, Sweden, Netherlands, Spain, Finland, Belgium, etc.). However, a few countries (such as Germany) keep a holding model where *DB Netze* is in charge of infrastructure management within the whole *DB* group. Other countries, like France, opted for a separated structure, where some of the tasks allocated to the infrastructure manager were allocated to the rail operator *SNCF*. In this case the model is indeed closer to a holding structure rather than a separated structure.

Restructuring Measures at Horizontal Dimension

The second dimension on the rail restructuring process is the introduction of competition in rail markets. There are basically two ways to introduce competition in rail markets:

1. The tender concession model for a particular rail market (competition *for the market*)
2. The open-access or free entry model (competition *in the market*)

The first model has been applied to many passenger regional services in some countries (especially in the United Kingdom, Sweden, Germany, Denmark, Netherlands, or the Czech Republic). Only long-distance services were offered by this model in a few countries such as the United Kingdom or Sweden. However, many of the incumbent operators are still publicly owned, and keep considerable power to influence the tendering results or to introduce barriers against potential competitors. Therefore, except in a few cases like the United Kingdom or Sweden, most of the tendering processes in Europe were awarded to the incumbent rail operators. The open access (or competition in the market) has been less used in the passenger sector. Casullo (2016) identifies 15 countries where open access is allowed, but only in 6 (Austria, Czech Republic, Germany, Italy, Sweden, and the United Kingdom) has the competition between different operators in the market been effective. As a final result, except for the United Kingdom, Poland, and Italy, the market share of competitor in the passenger market is below 20%, indicating the lack of success of these measures (European Commission, 2016; UNECE, 2018).

The open-access model has been the model developed for the freight market. In this sector, the entry of new operators has been more successful than in the passenger market. In fact, and from data provided by UNECE (2018), for seventeen European countries in 2014, the market share of competitors was in a range of 20%–55%. Furthermore, the market share of competitors in the freight market increased in 19 European countries from 2011 to 2014, decreased in only three countries and remained constant in four countries. However, except for Sweden and the United Kingdom, the market share for the incumbent remains dominant also for the freight market.

Approaches to Measure the Productivity in the Rail Industry

Productivity can be estimated as a measurement of the behavior of a firm. In particular, productivity can be expressed as the ratio of output with respect to the inputs used in the production process. When all outputs and inputs are included in the productivity measure we can define an index of total productivity. One way to measure the productivity level is to define index numbers. These indexes are very easy to calculate, because it is the simple ratio between one output and one input. They have important limitations when firms are multioutput and multiinput, as happens in the rail industry. The choice of a single output or input to define the index numbers will produce a biased result, due to the absence of the rest of inputs or outputs in the analysis. A good example of this type of technique is the paper by Oum et al. (1998).

Alternatively, more sophisticated approaches like econometric methods or Data Envelopment Analysis (DEA) can solve this last drawback and allow for the incorporation of different inputs and outputs in the analysis.

DEA is a linear programming technique that calculates technical efficiency by measuring the ratio of total inputs employed to total outputs produced for each firm or entity. DEA identifies the most efficient firms providing a vector of outputs employing the least number of possible inputs. Each firm in the sample receives an efficiency score determined by the variance in its ratio of inputs employed to outputs produced with respect to the most efficient producer in the sample. DEA has been used extensively to assess productivity and efficiency levels for the rail industry (see for instance Cantos et al., 2010, 2012; Growitsch and Wetzel, 2009; Wetzel and Growitsch, 2006). The main advantage of this method is that we do not need to consider any assumption about the distribution of deviations from the frontier or to adopt any functional form for this frontier. The disadvantages are the sensitivity to the reference sample (efficient units are those with the best performance among the observed ones, but perhaps they would not be considered efficient if the reference set were changed) and the consideration as inefficiency for any deviation from the frontier.

In particular, the DEA approach assumes that for each period t there is a set of N railway system ($i = 1, \dots, N$). Each railway system produces a vector of y_i outputs ($m = 1, \dots, M$) using x_i inputs ($k = 1, \dots, K$). The measurement of technical efficiency (input-oriented) under constant returns to scale using DEA is obtained by solving the following problem for each period and each railway system (assuming constant returns to scale):

$$\begin{aligned} \text{Min } & \theta_j \\ \text{s.t. } & \sum_i \lambda_i y_{im} \geq y_{jm} \quad \forall m \\ & \sum_i \lambda_i x_{ik} \leq \theta_j x_{jk} \quad \forall k \\ & \lambda_i \geq 0; \quad i = 1, \dots, N \end{aligned}$$

From the solution of this problem for each one of the N rail systems of the sample we obtain N optimal values for θ . Each value for the parameter is the input-oriented technical efficiency measure of each rail system which, by construction, satisfies $\theta \leq 1$. Those rail systems with $\theta < 1$ are considered technically inefficient, while those with $\theta = 1$, are cataloged as technically efficient, since they stand at the frontier.

Econometric methods can propose either the estimation of a cost or production function. The estimated function can then be used to identify changes in productivity or productive efficiency. A number of studies have applied deterministic or stochastic frontier methodologies to the rail industry. The drawback to estimate a cost function is that information on input prices and financial data is needed. In case of the rail industry, these data are difficult to achieve. This is the reason why production function is a more common analysis in the rail industry. Only physical data on outputs and inputs are required. Recent advances in econometrics have developed new approaches, such as like the distance function, which allows for the introduction of several outputs in a production function.

Assume that the production technology is defined by a vector Y of m outputs, as in the DEA approach, that can be produced by a vector X of k inputs. The output distance function is defined as $D_O(X, Y)$, which is nondecreasing, positively linearly homogenous and convex in Y , and decreasing in X . The output distance function is by definition linearly homogenous in outputs, which is imposed by dividing all outputs by one of the outputs. If we adopt a transcendental-logarithmic function (TL), the distance function to estimate can be expressed as follows:

$$-\ln y_{mi}^t = TL(x_i^t, y_i^t / y_{mi}^t, t; \beta) - \ln D_O^t(x_i^t, y_i^t)$$

Setting

$$u_{it} = -\ln D_O^t(x_{ij}, y_{it})$$

and adding a stochastic error term (v_{it}), the specification is similar to that of a parametric stochastic frontier with a decomposed error term:

$$-\ln y_{mi}^t = TL(x_i^t, y_i^t / y_{mi}^t, t; \beta) + u_{it} + v_{it}$$

where u_{it} is a nonnegative random error term representing the time-varying technical inefficiency. Finally, the technical efficiency is calculated as

$$TE_{it} = \exp(-u_{it}) = D_O^t(x_i^t, y_i^t)$$

An Empirical Assessment of the Rail Reforms in Europe

As a starting point, a first and interesting way to measure the scope of the liberalization process in the European rail industry was the elaboration of a series of indexes developed in 2002, 2004, 2007 and 2011 by IBM (2002, 2004, 2007, 2011). In these studies, different indexes on rail performance were developed according to three dimensions: the legal development of the industry (LEX), the degree of access permitted by the industry (ACCESS) and the level of competition (COM) within the rail industry. The LEX index assesses the degree in which the EU directives have been transposed to the legal system in each particular country. The ACCESS index values the degree in which a country has implemented the appropriate measures to promote the access of new rail operators in the country. Finally, the COM index measures the extent to which nonincumbent operators have managed to enter the market in an

effective way, valuing the number of new operators and their share in the rail market. The indexes are ranked between 0 and 1000, so that a higher score indicates a better performance in the area analyzed.

Analyzing the evolution of these indexes, the average value for the EU-25 for LEX and ACCESS has increased and the values for these indexes are relatively high (800 and 683, respectively) for the last year. However, the COM index has evolved negatively, with a value of 429 for the last year. The final conclusion is that most European railways have made notable progress in the implementation of the legal and procedural aspects of the European Directives. However, progress in introducing more competition in the European rail market, especially in the passenger sector, has been poor. Summarizing, the sector remains strongly concentrated and characterized by a very low number of new operators and the persistence of big market shares for incumbent operators.

Regarding the separation between infrastructure and rail operations, the findings obtained by the literature are not conclusive. Cantos et al. (2012) obtain, using DEA, that rail systems which separated infrastructure from rail operation are slightly more efficient than integrated more rail systems. Furthermore, the authors find that a higher increase in efficiency is produced when vertical separation is combined with the introduction of competition (using a tendering process or an open access system). A similar result is obtained in other works (Affuso and Newbery, 2002; Friebe et al., 2003, 2010; Jensen and Stelling, 2007; Merkert et al., 2012).

In this line, this result suggests that separation is a good measure to prepare and to promote the introduction of competition in the rail market. Similarly, countries that did not separate their industries vertically emerged as the most inefficient, although the improved efficiency in countries that only restructured vertically is very modest compared to those that have also embarked on horizontal separation. However, the scarcity of examples with a mixed approach (such as in Germany or Switzerland) where an integrated structure is combined with the introduction of competition prevents us from finding clear evidence of the benefits or otherwise of a more integrated system. This would explain the results of the studies in the United States freight industry, where separation barely leads to small efficiency gains (Bitzan, 2003; Ivaldi and McCullough, 2004, 2008). Nevertheless, other authors like Abbott and Cohen (2017) suggest that in Europe separation may have produced improvements in productivity, simply because so many national rail industries started from levels of low productivity in the first place.

However, many papers find that a separated vertical structure leads to additional costs which could be greater than any benefits derived from improved efficiency driven by competition. Clearly, close coordination between train operation and track maintenance is key to guarantee a reliable and efficient rail service. Additionally (see Pittman, 2005), there is a technological interdependence between infrastructure and vehicle technologies. In fact, rail tracks are designed depending on particular users, and these may be different whether they are used for high-speed trains, passengers in general, or freight and bulk services. In a separated structure, an infrastructure manager would be reluctant to undertake long-run and specific investments without a clear and a long run agreement with specific users. This risk is clearly minimized when the rail structure is integrated in the same entity.

The loss of these coordination effects or scope economies of vertical integration is the main danger of a separated structure. Additionally, there can be a reduction in the incentives to provide appropriate track maintenance and new capacity in the long run (see Bitzan, 2003; Growitsch and Wetzel, 2009; Ivaldi and McCullough, 2004, 2008; Merkert and Nash, 2013; Merkert et al., 2012; Wetzel and Growitsch, 2006).

Finally, some papers (Nash et al., 2014; Mizutani et al., 2015) find evidence that these coordination costs depend on the density and type of traffic. They find that these costs are notably higher if networks are highly used. Therefore, the costs of separation are significantly greater in densely populated areas. This occurs because management and scheduling costs are considerable when traffic density is also very high.

Summarizing, the final evaluation of the benefits coming from a separated structure will be an empirical task. The efficiency gains flowing from a separated structure with a higher and intense competition should outweigh the loss of coordination effects or economies of scope that the separated structure will produce. This may explain why the results obtained by the literature are not totally conclusive, stating in many cases that an integrated or separated structure is not necessarily a key factor in achieving an efficient rail system.

Finally, we present the results regarding the analysis of the measures to promote competition in the rail market. As we explained before, these measures have basically consisted in the introduction of a tendering system for some regional passenger services, specially regional or noncommercial services. However, in the freight sector the process has consisted in the direct entry of new operators, and this process has been undertaken in a larger number of countries. In general, most of the papers which have assessed these measures (Cantos et al., 2010, 2012; Driessen et al., 2006; Link, 2016) find evidence of the positive (but small) effects derived from more competition on the productivity of railway systems. The effectiveness of competitive tendering undertaken in the passenger sector largely depends on the right design of the bidding process favoring the most economically efficient operators and making sure that this efficiency gain is passed on to the society through lower subsidies. The experience of those countries who are most advanced in this measure has been positive (Germany, Sweden, The Netherlands, and United Kingdom). In the case of the entry of new operators in the freight sector, there is evidence that this process has revitalized the rail market, improving the rail market share and the productivity of the rail sector. Lastly, there is little evidence regarding the analysis of free entry (open access) in the passenger sector. New experiences of competition in the passenger market in Italy, Czech Republic and Austria have not led to conclusive results in the effectiveness of this measure (Casullo, 2016).

Conclusions

The rail industry is characterized by particular and economic features that in turn will influence their performance and technical behavior. Rail infrastructure fulfills the conditions of natural monopoly, while rail operations mostly fulfill the conditions for a

competitive market. This has been the economic rationale to favor the separation between infrastructure and rail operations in Europe. Additionally, some measures at horizontal level have been developed to promote internal competition in the European rail market. These measures have consisted in the introduction of franchising systems in the passenger sector (mostly regional or noncommercial services) and of free entry in the freight sector, although recently there are some experiences of competition in the market in some commercial passenger services. The evaluation of these measures is a key element when assessing the effectiveness of European rail policy, and for this reason we have carried out a range of different approaches and methodologies in this analysis.

A separated rail structure should favor the introduction of competition in the rail market improving the technical and financial performance within the sector. However, there is important evidence that a separated structure will increase the operational costs due to a loss of coordination effects between infrastructure and operations. Besides, there is clear risk of lower maintenance of the rail track and provision of new capacity in the long run following such a separated approach. Taking into account this tradeoff, the literature has provided mixed and far from conclusive effects on the effectiveness and productivity of this measure. Regarding the changes in the horizontal level, most of the papers show that, in general, the results have been largely positive. In the passenger sector, an appropriate design of the bidding system is key to making sure that the process can guarantee an efficient outcome. In the freight sector, a nondiscriminatory competition system between the rail incumbent and new operators is also essential in order to achieve favorable results.

Cost Structures for Automated Vehicles in Switzerland	508
Cost Structures in an International Comparison	511
Survey on People's Intention to Use Automated Vehicles	511
Outlook	512
References	512

Introduction

The expected arrival of automated vehicles (AVs) (SAE level 5) has the potential to drastically change the transport system. Given the 100-year experience with current vehicles, and the incremental acceptance to the new technology then, there is an urgent need to use the chance of the AV arrival to think about the regulatory framework upfront and the local goals for the transport system.

The wider discussion would have to answer at minimum the following questions:

- How do we want the transport system to be operated? At user equilibrium with all its externalities or at system optimum, but with the restrictions this would bring.
- What market structure do we want to allow? An anarchic individualistic ownership of vehicles, an oligopolistic set of fleet owners, or finally a local, maybe municipally owned, monopolist.
- How do we want to provide the transport for the low-income groups? Do we rely on the drop in costs/prices or do we still subsidize services, but how (person-based; service-based).
- Do we still need large vehicles transport large groups of persons (busses, street cars, light rail, heavy rail, etc.) and if so, where and when?
- Finally, what speeds/accessibilities do we want to achieve?

In this contribution we report results that can help in this discussion: comprehensive cost per person kilometer estimates for AV in Switzerland and worldwide; survey results on the likelihood of AV acquisition and use. These numbers and the estimation approach can help in the simulations needed to answer the questions, because the cost estimates will allow us to assess, if and how transport services could be provided sustainably by commercial firms or if subsidies are required.

The rest of the contribution is divided into three parts: first, the presentation of the cost estimation approach, then the international comparison. The third part discusses current survey results on the willingness to forgo a private vehicle in the presence of AV taxis. We conclude with an outlook.

Cost Structures for Automated Vehicles in Switzerland

The work presented by Bösch et al. (2018) provides a picture of the future cost structure of different (automated) transport modes for the Zurich, Switzerland area. It assumes that driverless vehicle technology is user ready and has already reached full market penetration.

First, the cost structures of private cars, taxi services and mass transit public transport (PT) (trains and buses) were reconstructed for the Zurich area. Where available, real data were used as a source. If not available, expert estimates were made based on aggregated data or background information. The cost effects of electrification and automation were estimated with a bottom-up approach.

For detailed cost factors (e.g., fuel or insurance) the expected changes were estimated based on literature or educated assumptions. These estimates were concluded with a calculation of variable and fixed provider costs and user prices per vehicle kilometer.

To estimate the resulting cost and price structures, however, the expected usage of the different services is required. It enables the distribution of the fixed costs, variable cost of support kilometers driven, and of variable costs per vehicle kilometer on the users. Based on the Swiss microcensus, the national travel diary survey, (Federal Statistical Office (FSO) and Federal Office for Spatial Development (ARE), 2012), and different usage studies, these values were estimated for the Zurich area. This allowed to calculate the resulting provider cost and user price per passenger kilometer.

For the already existing modes (private cars, taxi services, and mass transit public transport), these resulting prices were validated against current prices. While for private cars and public transport the estimated and observed prices matched well, for taxis it could be

Figure 1 Future competitive situation with autonomous vehicle technology in an urban and a regional setting. (A) Future competitive situation—urban setting. (B) Future competitive situation—regional setting. Source: Bösch et al. (2018)

shown that for Zurich Uber prices are likely too low (i.e., they are likely subsidized by Uber or the drivers are not considering their full cost) and that the taxi prices are likely at the upper bound.

Results show that private cars still represent an attractive option in the era of autonomous vehicles, since out-of-pocket costs for the user (0.17 CHF^a/km, i.e., \$0.27/mile, cf. Fig. 1) are lower than for most other modes (and could be even lower if the user, e.g., produced its own electricity). This is in the range of the \$0.15/mile Burns et al. (2013) found for shared AVs and the \$0.16/mile Johnson (2015) found for purpose-built automated ride-sharing vehicles, but they neglected important cost factors—for example, cleaning—found here to amount to 30%–50% of the cost of such a service. Compared to the assumption by Fagnant and Kockelman (2015) of a \$1.00/mile price for a shared AVs or the only 30% reduction to today's taxi prices suggested by Wadud (2017), even the full cost of private vehicle ownership might be competitive.

In fact, buying an autonomous vehicle could be regarded as an investment in a private mobility robot, which can be used both for chauffeur services and for errands; this choice will therefore be even more attractive than a conventional vehicle. Hence, it can be expected that a substantial number of people would value the private use of a mobility robot and will agree to pay the associated premium. Additionally, traditional car manufacturers are strongly motivated to maintain the current emotional connection many people have to their cars (Fraedrich and Lenz, 2015). In conclusion, even as low costs for shared AVs, as estimated by Burns et al. (2013) and Johnson (2015), might not be low enough to end the reign of the private car.

In contrast to private vehicle ownership, the results suggest that current line-based public (mass) transportation will probably be subject to adjustments beyond its automation. Although its operation will become cheaper, ride-sharing schemes and other new forms of public transportation will emerge as new and serious competition. The results also indicate, however, that the situation is not as clear as suggested by Hazan et al. (2016), for example. If full cost of shared vehicles is considered, combined with the low average occupancy achievable with ride sharing even in an urban setting (International Transport Forum, 2015), mass transit public transport is still competitive—especially for urban settings and high-demand routes—and even more so, if low-demand routes can be served with more flexible services, thus increasing average occupancy. The situation gets even more interesting if one considers that today's form of public transportation in Switzerland receives subsidies for approximately 50% of its operating costs (Laesser and Reinhold, 2013). In principle, with autonomous driving technologies and constant levels of subsidies and demand, operators would be able to offer line-based mass-transit public transportation for free at the point of use.

Shared aOS vehicles are seen by some researchers as an ideal first-and-last-mile complement of mass-transit public transportation. Offering direct point-to-point service for single travelers, they promise short access and travel times. However, they are not much cheaper to operate than shared midsize vehicles (Fig. 1). Policies aside, it is therefore more likely that fleet operators opt for a homogeneous midsize or van fleet to serve individual travelers, as well as smaller groups. One vehicle size functions well, particularly because—assuming acceptably low waiting times—few relations see a demand as low as only one traveler per time interval.

^a 2016 exchange rates (ER) (Organization for Economic Co-operation and Development, 2017a) and purchasing power parities (PPP) (Organization for Economic Co-operation and Development, 2017b): Swiss Francs (CHF)/US\$: ER 1.0, PPP 1.2.

Fleets of shared AVs (ride sharing or aTaxis) are another mode often proposed as the new “jack of all trades” in transport: offered at such low prices that they will replace every known mode. As this study shows, however, this picture changes if full costs, including overhead, parking, maintenance, and cleaning, are considered. Just these factors, neglected in most studies on the topic so far, contribute more than two-thirds of the total cost of aTaxis. It is thus no surprise that our estimates of the costs of shared services are substantially higher than those in previous work (e.g., Burns et al., 2013; Hazan et al., 2016; Johnson, 2015; Stephens et al., 2016). Because shared AVs are still very economical to operate and OEMs might also have an interest in shared services (Abhishek et al., 2016), these business models might still have a bright future. Shared fleets of aTaxis also have the advantage that the usage can be controlled and (geographically) restricted—especially compared to privately owned vehicles. This minimizes the liability risk for OEMs and mobility providers as long as AVs are not yet an established and proven technology.

Ride sharing might lower prices if high average occupancies can be achieved. High occupancies, however, come with more detours, longer individual travel times, and more strangers in the same intimate environment of a car. Especially the last factor might be an obstacle to the success of midsize or van ride-sharing fleets. People usually prefer the privacy of their own vehicle to the anonymity of a bus ride, and many find sharing a ride-sharing vehicle with strangers burdensome (Schmid et al., 2016). In this respect, more research is required to better understand customer preferences and design ride-sharing vehicles accordingly, because, if successful ride sharing with AVs will definitely have a number of benefits (Friedrich and Hartl, 2016; International Transport Forum, 2015).

A further challenge for shared services will be to find a solution to maintain vehicle cleanliness. The analysis mentioned earlier revealed that even with low cleaning frequencies and costs, cleaning is the single largest contribution to the operating cost of autonomous (individual) taxi schemes. Any higher level of soiling may even endanger their competitiveness through high costs or low service standards.

The work by Bösch et al. (2018) is—to date—the most comprehensive approach to estimating operating costs of future autonomous transport services. It includes several aspects previous studies have overlooked, or assumed negligible (e.g., overhead costs or cleaning) and it draws a clearer and/or different picture of the future transportation system than earlier works (Burns et al., 2013; Fagnant and Kockelman, 2015; Hazan et al., 2016; Johnson, 2015; Litman, 2015; Stephens et al., 2016; Wadud, 2017). While this detailed approach reveals new insights, it also comes with some limitations.

For example, it is likely that vehicle automation will change the mobility behavior and the demand for certain kinds of infrastructure, such as parking, which could require the government to take measures to counterbalance negative effects. The impact of governmental policy measures has been ignored in here; attention to policies was restricted to those already implemented today. Extended services, such as non-driving personnel in the vehicles or premium vehicles, have been ignored too. While such measures, policies, and extra services are expected to substantially influence price structure and thus the competitive situation, their cost will probably be passed along to the user. It follows that they would not substantially influence the basic cost structure of different services for the provider.

While the cost structures of cars, whether private or as shared vehicles, could be analyzed with a high degree of detail, the overhead costs of shared mobility services are well-kept secrets within the respective companies. Accordingly, estimates of the overhead cost of shared services and total costs of public transport services as well as the proposed savings must be treated with caution.

The same applies for the cost effects of new technologies. Electric cars are already on the market and thus estimates of the cost effects are reliable and well grounded. The effects of automation, however, are uncertain. Admitting this, the approach taken identifies different factors resulting in the observed total cost. Then, the effect of autonomy is estimated for each cost factor separately, resulting in more precise and reliable estimates. Where available, these estimates were based on values reported in literature. Even such detailed estimates’ accuracy, however, is questionable. Correspondingly, usage values are based on current market situation and price structures. If radically lower costs are assumed, these values are likely to change substantially (e.g., lower occupancy or longer trips). Once travel behavior impacts and usage patterns of such schemes become clearer, the framework introduced in this research can be used for a scenario-based analysis of their cost structures and will probably yield more accurate results. Until then, the reader should be aware of these limitations when interpreting the results presented here.

In conclusion, it is clear that fleets of shared autonomous vehicles may become cheaper than other modes in relative terms, but, in absolute numbers, the difference will be small. Thus, there will still be competition by other modes and even by private car ownership, which may well persist beyond the dawn of autonomous vehicle technologies by offering the luxury and convenience of a personal mobility robot. On the other hand, this research was able to confirm expectations (e.g., by Meyer et al., 2017) that conventional forms of public transportation may face fierce competition in the new era. Importantly, this research also revealed that the success of shared AV fleets may well depend on a factor which has been previously ignored—cleaning efforts. According to the findings, developing viable business models for shared AV fleets will entail solutions to require that customers behave appropriately while on board (e.g., video observation of passengers, or a confirmation check by the next user on the condition of the car to identify irresponsible passengers) and/or to clean and repair vehicles efficiently and at low costs.

Based on an exclusively cost-based approach, the work presented here was able to shed some light on the potential of different future modes. It is clear, however, that many open questions remain and that further research is required. For example, the identified cost numbers represent average numbers. Individual users might use a mode more or less than assumed here and thus the resulting price per passenger kilometer might change substantially for them. For example, two-thirds of the price of a private car (0.30 of total 0.47 CHF/passenger kilometer) are fixed costs. If the car is used more often than assumed here, these fixed costs will become lower per passenger kilometer, and, if the car is used less often, it will be more expensive.

A similar observation applies to public transport vehicles. The average occupancy of a city bus today is 22.42 passengers (Federal Office of Transport, 2011), and the threshold between a minibus and a city bus is at 21 passengers. This means that in average, in the future, a city bus is still the most cost-effective mean of transport for cities. Since this is in average only, lines and usage patterns need to be differentiated spatially and temporally. A detailed analysis is required to determine where this threshold of 21 passengers is crossed, and where much smaller vehicles will be sufficient.

Another important limitation is that the actual mode choice is determined not only by cost, but also substantially by travel time and comfort (value of time), as well as other factors such as the perception of transfers, waiting times, etc.—all of which are not investigated here. Therefore, actual implementations of the proposed schemes need to be tested in a field trial or simulation approach to better understand the size of the respective market segments in a realistic environment.

Cost Structures in an International Comparison

Vehicle automation and electrification substantially change the economics of mobility services. Compared to conventional vehicles, they overcome the need for a driver, reduce marginal cost (such as fuel consumption and depreciation), but their acquisition cost is usually substantially higher (due to technology and batteries). Given the large variation in purchasing power and salaries, the net effects will depend on the local context. Hence, a simplified version of the approach by Bösch et al. (2018) was applied to 17 locations in 15 countries across all continents. The results provide insights into the potential global market for AVs.

It is assumed that any future transport service will fall into one of the four following categories:

- Private vehicles,
- Individual taxis,
- Pooled taxis/dynamic on-demand public transport, and
- Line-based public transport.

Here, *private vehicle* describes the use of vehicles similar to today's private cars, whereas *individual taxi* will be like current taxi or ride-hailing services, just without the driver. *Pooled taxis* and *dynamic on-demand public transport* will provide point-to-point trips (potentially involving a short access and egress walk), but the vehicle will be shared with a small number of other passengers for at least parts of the trip. Midsize vehicles or vans can be expected to be used for this service. Finally, *line-based public transport* is comparable to today's public transport operated with large buses, trams, or even trains. All services are considered independent of any contractual frameworks or subsidies.

The results clearly indicate that, in general, vehicle automation will have a much more profound impact on cost structures of all services than electric propulsion, which may only allow cost savings of up to 10%. As in the Swiss analysis, taxi costs are reduced substantially by vehicle automation, whereas effects on public transport are lower. For private cars, cost reductions are only marginal. In some cases, higher acquisition cost due to the new technology cannot even be compensated by savings in marginal cost (leading to higher overall cost).

Differences between the different locations can be mostly characterized by the relative importance of costs for assets (vehicles) and salaries, respectively. In developing countries, current production costs are mostly driven by the former, so that additional investments in technology (sensors, processors, batteries, etc.) have a much stronger impact. In turn, in developed countries, labor costs are the key component, outweighing costs for (acquisition and maintenance of) the vehicle. Consequently, in many industrialized countries production costs for pooled taxi services will reach a level comparable to automated public transport. Individual taxis will still be more expensive than public transport, but, in absolute terms, the difference may not be substantial. In contrast, in many developing countries, the price difference between public transport and taxis will still be substantial.

A more quantitative analysis of the cost drivers shows that the median net per-capita income can already explain more than 50% of the variation in production costs of conventional services. Moreover, taxis are about a factor 4 more expensive than buses and difference increases with growing income levels. However, in an automated-electric regime, the absolute difference in cost is much lower and independent of the respective income level. This means that the absolute cost of transportation services will be almost the same across the globe, to the advantage of higher-wage countries, where automated taxis may become an everyday service. In lower-wage countries, disruptions can be expected to take much longer to set in. Hence, both development of new business models as well as policy efforts to manage transport demand can be expected to take place in few, higher-income countries first.

Survey on People's Intention to Use Automated Vehicles

AVs are likely to play a crucial role in transport systems once the technology is developed and regulation has been adjusted. This can be reasoned with their higher comfort compared to currently available modes and an increased safety if the technology outperforms human drivers. It is therefore important to continuously monitor the public's opinion on that development and to investigate how people intend to change their mobility behavior and tools early. A survey conducted in 2018 intended to answer these questions for the Canton of Zurich, Switzerland. It focused on vehicles with SAE-automation-level 5, meaning that they are able to perform empty rides.

In line with predictions from car manufacturers such as BMW and Ford, the survey distinguishes between two different development steps. In the first step, it is assumed that vehicles are only available on-demand and cannot be bought privately. In particular, the AVs are either available as taxi automated vehicles (TAVs), that is, sequential car sharing, or pooled automated vehicles (PAVs), whose service involves simultaneous car sharing (ride sharing). Due to detours and higher occupancies, PAVs are assumed to be slower and cheaper on average. In the second step, respondents are also given the opportunity to buy AVs.

The survey has three paper-based stages and follows a pivot design. In the beginning, respondents are asked about their portfolio of mobility tools (such as cars, bikes, and season tickets) and information about a short (<50 km) and long trip (≥50 km). Afterwards they are asked how they intend to change their portfolio of mobility tools once on-demand AVs are available (development step 1). They further complete a mode-choice questionnaire for this step. The process is repeated for development step 2, which includes on-demand services as well as private AVs.

The availability of the alternatives is adjusted to the trips and mobility tools and the base levels of the attributes reflect the real choice situation. Costs for AVs are based on the cost calculations presented earlier. The possible alternatives are classic public transit (PT), public transit with an SAV feeder (PTAV), bike, walk, conventional car, SAV, and PAV.

If only on-demand AVs are available, the number of conventional cars per household drops by 30%. However, if people are also given the opportunity to buy AVs, no statistically significant effect can be observed regarding the number of cars. In contrast, half of the conventional cars were replaced with AVs.

Price changes for on-demand services in the bandwidth of ±30% do not have a significant influence on people's decisions regarding their mobility tools. For public transport subscriptions, no significant changes among the development steps could be observed.

The results from the mode-choice experiments show that people mainly switch from the conventional car to automated modes. Nevertheless, the conventional car remains the dominant mode if only on-demand AVs are available to travelers. PAVs and TAVs are each used for around 7% of the short trips. Once the respondents are able to use private AVs, conventional cars and private AVs are each used for approximately 30% of the trips. The public transport usage remains relatively stable.

The model results further show that people are less inclined to pay for reducing the travel times of AVs compared to the conventional car. While the value of travel times savings of the conventional car amounts to 30 CHF per hour, the respective values of private AVs and TAVs amount to 24 and 20 CHF per hour, respectively. One reason for lower VTTS values is an increase in comfort, since the driver can perform other tasks while being chauffeured. At 12 CHF per hour, the VTTS for public transport are still lower.

To conclude, the respondents in this sample are willing to use AVs once they become available. At this moment, the majority of those intending to use AVs are still inclined to use their own vehicle rather than sharing solutions.

Outlook

This first result indicates that commercial AV taxi-based services might have a hard time between the comparable costs of privately owned AVs and the needs to transport large numbers of persons in dense urban areas; unless, the capacity gains due to the AVs are so large, that the increasing number of vehicle kilometers can be accommodated at reasonable speeds (Loder et al., 2019).

It is clear that the work on answering the questions raised earlier has only just begun. The cost estimates will change as technology matures. The assessments by the potential users and vehicle ownership will evolve as the market continues to change.

Still, the need for a comprehensive simulation approach is clear.

Overview

Economic agents typically do not take into account the social cost of their choices or actions, that is, the cost they impose on society. When it comes to transport-related choices this often translates, for instance, into using private rather than public means of transportation, larger rather than smaller vehicles, more rather than less powerful engines.

In the 1920s, Economist Alfred Pigou introduced a concept that became known as Pigouvian tax, which can be seen as an attempt to discipline economic agents. Specifically, if an economic activity generates costs to third parties (external social costs), regulators should introduce a tax equal to the external social cost of such activity, or externality. This arguably simple framework is the starting point of most economic analyses of environmental problems to date.

Determining the level of the tax is, however, a nontrivial task for a number of reasons. First, one has to identify the factors generating external social costs. This could include carbon emissions from transportation, but also local pollution generated by combustion engines and tires, costs of congestion, accidents, noise and visual pollution caused by driving, wear-and-tear of roads, etc. In recent years, it has been identified that, in some jurisdictions, some external costs have been given more importance than others, which may benefit one technology in detriment of another. Concretely, the EU legislation has historically been relatively strict in terms of CO₂ emissions but more lenient with regard to local pollutants, which was documented to benefit diesel in detriment of gasoline vehicles (Miravete et al., 2018) and thus European rather than non-European manufacturers.

Second, one has to correctly quantify each of the earlier externalities. Recent evidence of the manipulation of driving tests led credence that measurement is potentially of first-order importance, especially in diesel vehicles, which led to the recent redesign of test cycles in Europe.

Third, one has to assign monetary values to each of the earlier factors. For instance, local pollution generated today might have long-lasting health effects current research was not yet able to identify.

Fourth, the passing on of taxes onto prices depends on both the competitive structure and on the characteristics of the supply and demand profiles of a particular market. In particular, firms may or may not pass on the cost of a tax to consumers.

Fifth, it assumes that consumers correctly quantify and take into account in their decisions the tax levied on their activities or the products they purchase (Huse and Koptuyug, 2018).

Despite the earlier limitations, the Pigouvian framework provides the basic tool kit used by economists and regulators in the analysis of environmental problems, also in the transport sector. If carbon emissions are the only external cost of transport imposed on society, then the Pigouvian tax is efficient (or first-best), in that it imposes on consumers the entire external costs their activity generates to society. In particular, a fuel tax is a Pigouvian tax in this specific case, as introducing it tackles both utilization (kilometers driven) and fuel consumption (how many liters a vehicle requires to drive 1 km) of a driver-vehicle combination.

An additional factor making taxes appealing is that they are cost-effective, in the sense that they satisfy the Least-Cost Theorem, an important result in environmental economics. That is, taxes are able to attain a given environmental target at least cost to the society, which results in an economically efficient allocation of resources. In more concrete terms, if a policy instrument is least cost, then it satisfies the so-called equi-marginal principle, according to which the cost of abating pollution is equalized among all polluters—in particular, economic agents for which abating pollution is cheaper will abate more than those for which abating pollution is more expensive until the cost of abatement of all agents equalize.

If consumers are not able to identify and/or quantify the extent of the taxation they are subject to, then they will undervalue the fuel tax and overutilize transportation. As a result, this is one channel through which the fuel tax loses its first-best property. Therefore, additional policy instruments are called for, such as standards or vehicle taxes. Although they do not tackle utilization, standards have an impact on the fuel economy (or fuel consumption) of a vehicle, making less efficient vehicles more expensive than their more efficient counterparts. Circulation taxes operate in a similar way, but while standards typically influence only the purchase of new vehicles, circulation taxes are charged yearly and thus affect both the new and the secondhand car market.

The distinction between new and used vehicle markets is crucial since while the former receives considerably more attention, it is only a small (typically single-digit) share of the latter. Thus, one has always to bear in mind the scope of the policy instruments aiming to tackle carbon emissions at the risk of said instruments not having a meaningful impact.

Recent events in the transport sector have brought back attention to local pollutants and shed light on a number of alternative policy instruments tackling pollution in transportation. If local pollutants are not addressed when determining the level of the fuel tax, then alternative policy instruments—especially those targeting diesel vehicles—are called for. These include congestion pricing and driving restrictions, which can occur in various forms.

Finally, considerations about optimal policies have to take into account the political constraints that often prevent a straightforward implementation of those measures. While interventions adopted by governments might not represent the most efficient practice from an economic viewpoint, they might be the only politically feasible solutions.

In what follows, we briefly describe the main policy instruments that can be used to mitigate carbon emissions and their applications.

Fuel Taxes

If the externality policy-makers aim to address is CO₂ emissions, more generally, greenhouse gases, a fuel tax typically charged on a per-liter or gallon basis is a Pigouvian tax on emissions and can thus achieve the first-best outcome in the absence of consumer undervaluation of energy (fuel) costs. Otherwise, to achieve a first-best policy one needs to combine a fuel tax with a standard and a car tax, at least in the case of a representative agent model. For alternative externalities, other instruments would be first-best. For instance, road pricing would address the congestion externality, a per-kilometer tax based on vehicle type might be first-best to address the accident externality and road wear-and-tear (Parry and Small, 2005). In case local pollutants are also considered, the design of policies becomes more complex.

Fuel taxes contribute to the reduction of vehicle CO₂ emissions in two ways: first, they induce drivers to reduce vehicle utilization; second, they push consumers to choose more energy efficient vehicles (Li et al., 2009). The timing of these two effects is different though. While adjustment in kilometers driven can occur within a short time frame from a tax change, the effect on the composition of the vehicle fleet is slower, as generally the increase in driving cost does not justify the immediate replacement of a vehicle. Nevertheless, the presence of two channels of emission reduction rather than only one makes fuel taxes often a better solution than other types of environmental regulation addressing only fuel efficiency, like standards or vehicle taxes.

The way consumers respond to fuel taxes when choosing a vehicle depends also on whether drivers understand correctly the role fuel price has on driving costs—which are also based on fuel economy and kilometer driven. Hence, the question whether a change of 100 in driving costs would be considered equivalent as a change of 100 in vehicle purchase price. Recent evidence on perception of fuel costs and fuel economy shows in general modest to no undervaluation, suggesting that consumers would be able to respond optimally to tax changes.

Compared to fluctuations in fuel prices due to supply-side shocks, fuel taxes have two relevant characteristics. First, any change is often advertised by the media and thus is more salient to consumers. Second, the taxes are more persistent over time. One important implication is that drivers might respond to changes in fuel taxes more strongly than an equivalent changes in pretax fuel price.

While reducing CO₂ emissions, fuel taxes generate considerable revenue. That led to assume the presence of a “double dividend,” in which not only fuel taxes would reduce externalities from carbon emissions (first dividend), but they would also allow to reduce other distortionary taxes like the income tax or to fund public goods (second dividend). However, the interaction between the environmental tax and other preexisting distortionary taxes can also exacerbate the efficiency loss caused by the latter. Whether this tax interaction effect dominates or not the effect of the second dividend depends on the characteristics of the fiscal system, and has important consequences on the optimal level of the fuel tax—whether lower or higher than the marginal damage linked to CO₂ emissions.

The practical implementation of fuel taxes, and carbon taxes in general, can be subject to significant political constraints. An important reason is that drivers tend to be more aware or attentive of fuel taxes than other vehicle policies (Huse and Koptuyug, 2018). Fuel taxes are often also introduced for other reasons, such as to fund infrastructure building and maintenance or as a general source of public funds. Furthermore, specific categories can be more affected than others. The impact over different income groups depends on the availability of automobiles among poorer households, and in general on the share of expenditure on fuel over the total household budget. Drivers living in urban areas can switch more easily to other transportation modes than those living in the countryside. Nevertheless, tax revenue can be used to mitigate those distributional concerns, for instance, through a lump-sum rebate, or through a cut of the income tax marginal rates (Bento et al., 2009). While politically challenging to introduce or change, fuel taxes represent one of the most direct and effective measures to deal with carbon emissions.

Fuel taxes are widespread worldwide, being adopted from EU countries to China, India, the United States, and several emerging economies. Two things are of notice, however, when looking at the levels of fuel taxes worldwide. First, according to OECD statistics for 2018, taxes on gasoline are higher than their diesel counterparts in the vast majority of the countries surveyed, sometimes substantially more so. Second, the value of the fuel tax varies considerably across countries.

Standards

Standards can equivalently be imposed on CO₂ emissions, fuel consumption, or fuel economy, as these are related quantities for a given motor fuel, given the physical relation between a vehicle's CO₂ emissions (measured in, say, gCO₂/km) and its fuel consumption (measured in, say, liters/km).

Standards impose a maximum value on the variable being regulated (a target) and, when binding, act as an implicit, revenue-neutral tax on the variable of interest (Knittel, 2012; Anderson and Sallee, 2016). The inefficiency of standards occurs due to the rebound effect. Additional externalities, such as congestion, will favor fuel tax.

That is, standards incentivize the purchase of more efficient cars but the resulting savings tend to generate an increase in vehicle utilization; dimension standards do not address. Intuitively, this can be shown as follows. Assume the only transport externality is CO₂ emissions, which are measured in grams of CO₂. A fuel tax influences both vehicle utilization (measured in vehicle-kilometers-year, say) and emission rates, whereas a standard affects only the latter. Thus, while the incidence of fuel taxes falls on all determinants of CO₂ emissions, that of standards fall only on part of them, which results in their inefficiency.

Standards apply to new vehicles and might or might not be passed on to consumers by carmakers, partly because of the highly concentrated market structure in the auto industry. Nevertheless, they incentivize the improvement of the regulated characteristic due to the change in relative prices between efficient and inefficient vehicles.

While traditionally standards applied uniformly across products, a number of countries have recently adopted attribute-based standards, according to which a target varies according to some attribute of the vehicle such as its weight or footprint (the rectangular area defined by a vehicle's tires). Typically, larger or heavier vehicles face a laxer standard, which implicitly subsidizes vehicle weight or footprint. Nevertheless, according to the US Energy Information Administration, attribute-based standards have been introduced in most of the major vehicle markets worldwide, including the United States, China, Japan, and Europe.

Vehicle Taxes

A vehicle tax is another policy instrument designed to tackle emissions-related externalities. To clarify matters, it is important to distinguish between a registration tax and a road (or vehicle circulation) tax (also known as vignette in some countries). A registration tax applies only to the first registration of a vehicle. Some prominent adopters are Spain, and South Africa, where the registration tax is set according to the CO₂ emission rate of the vehicle. By contrast, a road tax is to be paid every year by vehicle owners provided their vehicles are circulating (some countries allow vehicles to be periodically de-registered, e.g., during Winter). Thus, while a registration tax has an impact only on new vehicles, a road tax shapes the composition of the whole fleet. This distinction is important since a road tax has been found to impact vehicle retirement decisions and consumer choice in the used vehicle market. In some cases though, an introduction or a change of a road tax applied only to new registrations. That implied that older cars were still subject to previous regulations, often more lenient toward inefficient vehicles.

The vehicle tax is an explicit tax effectively paid by vehicle owners, just as it happens with the fuel tax and in contrast with standards. Typically, the tax is calculated based on vehicle attributes such as weight, fuel type CO₂ emissions, or sales price. This allows regulators some leeway in treating technologies differently. While such characteristics are already correlated with carbon emission rates, some countries based their vehicle tax system in part or fully on the CO₂ emission rate (gCO₂/km) of vehicles.

As it happens with standards, a vehicle tax does not influence utilization, and the marginal cost of driving decreases in fuel economy. For this reason, vehicle taxes are considered less cost-effective and less efficient than fuel taxes in reducing carbon emissions from the transport sector (Cerruti et al., 2019a). Nevertheless, they are often easier to implement from a political point of view, and their use is justified when consumers undervalue fuel costs—and thus fuel taxes—compared to other costs of buying and driving a car. Vehicle taxes directly or indirectly linked to CO₂ emissions have played an important role when it comes to technology adoption (gasoline vs. diesel vehicles) in the European car market, partially explaining the market share commanded by diesel vehicles in Europe (Klier and Linn, 2015; Miravete et al., 2018). Registration or sales taxes are widespread around the world, including Japan, China, India, South Africa, and most European countries.

Rebates and Feebates

Another monetary instruments available to governments to address environmental externalities are subsidies on the adoption of low-emissions vehicles, under the form of a discount on the purchase price (rebate). A rebate can be combined with a vehicle tax to form a feebate (fee + rebate), which often works in a self-financing manner. In practice, feebates are policy instruments used to alter the relative prices of high- and low-energy efficiency products. Fees are charged to vehicles emitting more than a given threshold

emissions level (the pivot point), whereas rebates are given to vehicles emitting less than said level (Adamou et al., 2014; Huse and Lucinda, 2014). Because feebates include a sales tax component, the considerations made for vehicle taxes in the previous section largely apply in this context as well. Feebates have been adopted in some European countries, noticeably France and Sweden. Rebates on low-emission vehicles are more widespread worldwide. Both types of policy have historically received substantial attention given the values involved, be it on a per-vehicle basis or in the aggregate.

When introducing rebates for low-emissions vehicles, policy-makers should pay special attention to the impact of free-riding and low pass-through rates. Free-riding occurs when part of the consumers benefiting from the rebate would have chosen a low CO₂ vehicle even without incentives, or when consumers take advantage of political or administrative borders. Such type of behavior decreases the cost effectiveness of environmental programs. In case of low pass-through rate instead, part of a rebate on final vehicle price might not benefit consumers, as car dealers and manufacturers would increase purchase prices accordingly.

Vehicle Scrappage Schemes

Governments can also incentivize the early retirement of old, inefficient, cars. Vehicle scrappage schemes offer a rebate on the purchase of a new energy efficient vehicle if a buyer trades in her old vehicle (Jacobsen and Van Benthem, 2015). After the Great Recession several countries (e.g., the United States, EU, Japan, and China) adopted these programs both as an environmental measure and as a temporary stimulus for the economy. The effectiveness of these incentives as a measure to reduce vehicle carbon emissions is still under debate. The short duration of the scrappage subsidies can exacerbate the free-riding problem. In fact, people might respond to the incentives simply by anticipating by a few months the purchase of a low CO₂ vehicle. If so, the environmental gains from the program will be likely modest compared to its costs.

Information Programs

In order for decarbonization policies to work, proper consumer information is essential. That means providing consumers with information on policy measures and vehicle characteristics, including carbon emissions, presenting such information in a clear and understandable way, and making sure that individuals are able to incorporate the information in their decision-making process. An advantage of information interventions is that they are typically less expensive to implement than other policy instruments. In several countries (e.g., the United States, EU, Chile, Japan, South Korea, and Australia), new cars on sale must display in a visible way the fundamental characteristics of the vehicle, usually contained in an “energy label.”

The way information is framed is also important. The CO₂ emissions rate (g/km) is a precise metric, but lacks a reference point for consumer to understand how a car fares in comparison to other vehicles. For this reason, some countries present CO₂ emissions according to letter rating framework (e.g., from A to G). While easier to understand, this simplified design might lead to misinterpretations, in particular when the rating is also based on other vehicle characteristics such as weight (i.e., an “attribute-based label”). Furthermore, information on CO₂ emissions and fuel economy, measured through laboratory testing, is often imprecise. Switching to better testing methodologies, like the recent replacement in the EU of the NEDC with the WLTP test, can attenuate the gap between real-world and measured values.

Although information programs are now widespread, they typically apply only to the new vehicle market. In fact, the use of outdated efficiency ratings in used vehicles, which tend to be upward-biased (e.g., overstating the efficiency of a used vehicle), might provide consumers with wrong information and thus hinder optimal decision-making.

Finally, providing comprehensive information is important not just for vehicle characteristics, but for environmental policies as well. In some instances, people might not be aware, or not have a full understanding, of the incentives in place for switching to low-emission vehicles (Cerruti et al., 2019b). For this reason, the implementation of vehicle taxes and rebates should coexist with appropriate information campaigns to clarify both the existence and the scope of those policies.

Congestion Pricing and Driving Restrictions

The policies considered so far have been implemented at the national or regional level, but they are generally precluded to local governments. Instead, municipalities have applied congestion pricing and restrictions to vehicle circulation in selected areas. In the vast majority of cases the goal of those measures is to reduce traffic congestion or local pollution, but by reducing traffic they might have an effect on carbon emissions as well.

While congestion pricing consists of charging vehicle owners a (potentially time-varying and vehicle-dependent) fee to get access to a certain area, such as the center of a city, driving restrictions only allow a subset of the vehicles to enter such area, sometimes called a low-emission zone. One variant is to restrict vehicles based on occupancy, so only vehicles with at least a number of passengers are granted access to certain lanes, called high-occupancy vehicle (HOV) lanes. While HOV lanes have been introduced mainly in North America, several cities worldwide have implemented either vehicle driving restrictions (e.g., Munich, Mexico City, Quito, and Shanghai) or congestion pricing schemes (e.g., London, Milan, and Singapore).

On the theoretical front, economic efficiency favors congestion pricing over driving restrictions; while the price mechanism inherent in the former allows flexibility and theoretically achieving a least-cost outcome, the latter can be thought of as being akin to licenses, resulting in a number of unintended consequences. Such pricing mechanism affects both distance driven and the vehicle stock, and in some cases might induce people to replace their vehicle earlier with a newer, more efficient vehicle with less driving restrictions.

In some cases, these policies might backfire. For instance, restrictions based on the last digit of the license plate number (odd or even) have prompted households to keep older vehicles longer and in some cases to have two vehicles—one ending with an odd number and another ending with an even number—to circumvent the regulation. While restrictions based on vehicles' emission rates of local pollutants have been shown to be more effective, there might be trade-offs between reducing air pollution and reducing CO₂ emissions. For instance, gasoline cars tend to emit less PM₁₀ and NO_x but more CO₂ than diesel cars.

Distributional effects are another important consideration: as typically driving restrictions and congestion charges are adopted in city centers and residents are granted free access or discounts on the charge, these policies tend to affect more people living in suburbs and commuting to the city. When driving restriction or fees are based on vehicle emission rates, low-income households who keep their older car for longer or who cannot afford to replace their vehicle would be disproportionately affected by the measures.

Mileage (or Utilization) Tax

Although not yet being implemented on a large scale in the context of passenger vehicles, interest in pricing directly vehicle distance driven has grown over the years. In part that is due to the availability of the GPS technology necessary to implement such tax, but in part it is due to concerns that, thanks to the improvements in vehicle energy efficiency, revenues from fuel taxes will decline over time. Because its simplest form does not depend on fuel efficiency, a mileage tax would have an effect on carbon emissions only through the reduction of kilometers driven, but it would not impact vehicle choice. Thus, from a climate policy standpoint it should be considered as a complement of fuel taxes, standards, and vehicle taxes, rather than a substitute (Parry et al., 2007).

Shortcomings of a mileage tax include the fact that it does not address congestion and its distributional effects, since they impose a heavier burden on rural households, who often have less access to alternative means of transportations.

Modal Transport/Public Transport

The provision of public transport services has the potential to affect vehicle use both in terms of intensive margins (how much to drive) and of extensive margins (the decision to buy a car). Moreover, mileage elasticity with respect to fuel taxes or congestion charges is affected by the availability of alternative transportation modes.

Currently, most public transport systems in the world are partially subsidized by local governments, and in Europe a number of towns have considered to introduce—if not already implemented—a zero-fare policy. The rationale for such government subsidies is that the substitution between transportation modes mitigates externalities associated with driving, including carbon emissions. Studies in different countries have indeed shown positive effects of public transport availability in terms of reduction in utilization, congestion, accidents, and air pollution (Anderson, 2014). Thus, it is arguable that positive subsidies toward mass transit are justifiable on efficiency grounds. The optimal subsidy amount likely depends on the existence of other measures aimed to reduce vehicle use, such as congestion charges or dedicated bus lanes.

Afterword

This paper briefly surveys policy instruments currently used in the transport sector. Given how mobility is believed to develop in the coming years, many new exciting questions arise. First is what will be the prevailing technology when it comes to mobility. Although electric mobility currently appears as the leading alternative to internal combustion engines, hydrogen-based alternatives should not be discarded in the long run.

Second, for a given technology to prevail, it requires charging infrastructure which itself might generate new externalities. For instance, in its current form, charging can become a challenge in cities where vehicles are parked on streets, demand for charging can eventually worsen congestion and force regulators and urban planners to rethink how cities are designed and operated.

Third, assuming electric mobility is to prevail, the precise quantification of its carbon footprint is paramount. Currently, batteries are manufactured using minerals extracted under often-unassessed conditions, and whose disposal and recycling calls for increased attention. Moreover, more should be understood about the potential impact of electric mobility on electricity prices as well as the continuing dependence of the carbon footprint of electric vehicles on the source of electricity, which can vary both across regions and even within the day for a given region.

Finally, the choice of policy instruments might be affected by how the business model of the transport sector will develop. For instance, whether vehicles will either be owned, leased, or rented, that is, if transportation will become a service and vehicles will be accessed through a subscription vehicle along the lines of a mobile phone or ISP subscription nowadays, whether batteries will become commodities and will be replaced rather than charged, and the extent to which autonomous driving will be prevalent. All

these aspects might have an impact on utilization, vehicle choice, and the speed with which vehicle owners respond to changes in policy instruments and thus on carbon emissions.

Biographies

Cristian Huse is a Professor of Economics at the Department of Economics, University of Oldenburg, Germany, where he holds the chair of Applied Microeconomics. His research interests comprise Applied Econometrics, Applied Microeconomics, Environmental, Energy, and Transport Economics, and Industrial Organization. His research has appeared in scientific journals in Economics and in the Sciences. Recent research examines whether consumers correctly value policy instruments, the choice of energy source in personal transportation, and the effectiveness of environmental policy in the transport sector. He is a graduate of the London School of Economics (PhD in Economics, MSc in Econometrics and Mathematical Economics), the Getulio Vargas Foundation (MA in Economics), and the Federal University of Rio de Janeiro (BA in Economics). His teaching experience includes courses in Econometrics, Environmental Economics, and Industrial Organization, at different levels.

Davide Cerruti is a Postdoctoral Researcher at the Centre for Energy Policy and Economics, ETH Zürich. His research interests include Applied Microeconomics, Public Economics, and Environmental, Energy and Transport Economics. His recent work evaluates the effect of the UK vehicle circulation tax on carbon emissions, and the consequences of low awareness about fiscal incentives for energy efficient vehicles. He holds a PhD in Agricultural and Resource Economics from University of Maryland and an MSc and a BSc in Economics from Università Bocconi, Italy. In the past, he worked also at the Energy Policy Research Group, University of Cambridge.

The Idea of Computable General Equilibrium Analysis

Computable general equilibrium (CGE) analysis is a mathematical tool for studying various influences from outside on virtually any relevant economic variable of an economy. The influences to be studied may be policy interventions such as taxes, minimum wages, tariffs, or transport policies of any kind: infrastructure investments, environmental levies and congestion prices, antitrust policies, network access rules, and many more. Influences from outside may also be technology changes or developments in the rest of the world affecting the economy under study through trade or factor flows. The method is a multipurpose weapon. One-fits-all designs of CGE models abound therefore in applied research. Naturally, however, such designs need to be complex. Small models with a design focused on the specific questions at hand might therefore be preferred. The method is applicable on any spatial scale, urban, regional, national, or global. There are good examples of applications on all these scales published in respected scholarly journals, for example, [Horridge \(1994\)](#), [Anas and Liu \(2007\)](#), and [Tscharaktschiew and Hirte \(2012\)](#) on the urban scale or [Bröcker et al. \(2010\)](#) on a European scale.

The “C” in the CGE acronym means “computable” or “computational” in a double sense. First, the instrument is used for quantifying policies or other impacts by simulating the response of the economy in a computer simulation. Second, this task is doable not just by studying hypothetical examples, but also by basing the simulation on real-world data. A common feature of CGE models is data replication, meaning that solving the model for a reference situation (the “benchmark”) should reproduce accounting data recording the economic transactions covered by the model in value terms. Data sources are national accounts, including input–output data and additional accounting information needed for the problem at hand. The impact study needs to compare the benchmark with an alternative resulting from inserting a policy intervention, a technology change, or what else is to be quantified. In the CGE jargon, such exogenous changes are called “shocks.”

In brief, the CGE analysis proceeds in the following three steps:

1. Designing a theoretical model implemented on a computer.
2. Determining model parameters in such a way that the relevant real-world accounting data are replicated (calibration).
3. “Shocking” the simulated economy by a policy intervention, technology change, etc.

What does the “GE” mean in the CGE acronym? It means that the model is a version of the general equilibrium model in mainstream economics, as explicated in advanced microeconomic textbooks, with certain extensions toward imperfect markets that may be found only in specialized literature. There is, however, a fundamental—often concealed—difference between the textbook model and the applied CGE, related to the difficult issue of aggregation. While the agents in the theoretical general equilibrium model are individual firms or households, agents in a CGE model are aggregates, for example, “firms” representing entire industries or “households” representing the entire private household sector in a region or country. In the special case of firms under perfect competition this jump from micro to macro is in fact justified, because a group of firms behaves like an individual firm, but in all other cases it is not. In certain cases one can go from micro to macro by the simplifying assumption that all firms in a macro-representation of an industry are identical except for the product variety they offer (see Section “Economies of Scale”), but sometimes one just closes the theoretical eyes when jumping from micro to macro.

Similarly, while commodities in the general equilibrium model are individual items of which myriads exist in a real economy, CGE commodities are aggregates such as cars, textiles, or even more aggregated objects such as manufactures or services. The main variables to be determined in a CGE are quantities of economic transactions (goods supply and demand, labor supply and demand, and so forth) and the respective prices. How can one define a price and a quantity of something that heterogeneous as manufactures, say, in a meaningful way? The trick is the so-called LEONTIEF convention: the benchmark price of the aggregate commodity (manufactures in this case) is arbitrarily chosen, for example, equal to one. The benchmark quantity is then simply

the value in the accounting data, divided by the price. In words: one unit of manufactures is the quantity that is worth one unit of money in the benchmark. After the shock both, price and quantity, change, and the after-shock value of a transaction is its after-shock quantity times its after-shock price. Though levels of prices and quantities do depend on the arbitrary choice, percentage changes do not. This concept of a “quantity” is a striking difference between modeling philosophies in CGE analysis and transport engineering. Transport engineers look at “real” quantities such as number of passengers or tons. This is a source of confusion between the two modeling communities and causes problems for linking models from the two worlds (see Section “Spatial CGE and Transport”).

The rooting of CGE analysis in mainstream microeconomics establishes a methodological link between traditional cost-benefit analysis (CBA) and project evaluation by CGE analysis. In classical CBA, infrastructure investment (building a road, say) is evaluated by subtracting the construction costs from the money-metric benefit measured by the consumer surplus of road users. The theory behind is that this is the utility gain, translated to an amount of money by the so-called Hicks variation, if the road user is a consumer (abstracting from the negligible income effect). If it is a firm, this is just the profit gain, which eventually shows up as an income gain in the pockets of households. If a service is affected that is privately supplied, in addition the producer surplus is to be added that also measures the profit gain of the respective firms. Exactly the same valuation measures are quantified in a CGE, though not evaluated “on the road,” but based on the utility changes of the households at the end of the adjustment chain triggering through the economy.

It is now—after a long and sometimes confusing literature debate about “Wider Effects”—well understood that under perfect competition both approaches deliver the same result, provided there are no technological externalities. It does not matter how indirectly households are affected, whether they are themselves the road users or buy goods transported along the road or buy goods that use goods transported along the road as inputs and so forth.

Hence, given that results should coincide, what can CGE analysis add to traditional CBA? First, the distribution of benefits and costs can be added. Multiregional models, to be discussed in Section “Spatial CGE and Transport,” allow for identifying the regional incidence of policy intervention, which is vital for policy issues such as cost sharing of infrastructure investment. Introducing households representing different income groups allows for quantifying the incidence across social strata, which is vital for a policy debate on transport policy and social justice.

Second, CGE is the method of choice if the two restrictive assumptions mentioned, perfect competition and no technological externalities, are violated. In case of imperfect competition, a well-designed CGE can identify the deviation between consumers’ surplus and households’ benefit, and thereby give a theoretically clean and data-driven answer to the wider benefit issue. A CGE is also helpful if indirect technological externalities are at stake, externalities that are generated by a transport policy intervention elsewhere in the economy, outside the transportation sector.

The Structure of CGE Models

A CGE has two constituents, the set of agents and the set of markets. Agents sell or buy goods and production factors to or from the markets. There are two types—firms representing the behavior of industries and households representing the entire household sector or segments of it. Agents act rationally; firms maximize profits subject to technological constraints, and households maximize utility subject to their respective budget constraints requiring that what they spend equals what they receive from selling the production factors they own and possibly from sharing in profits of firms. If the state enters the scene, it is modeled as a further household collecting taxes, paying transfers, and buying goods for public consumption and investment. Tax payments and subsidy receipts then have to be subtracted or added to the firms’ revenue, and taxes and transfers have to be subtracted or added to the households’ budgets. In any case, budget constraints must hold for all agents. Black holes where receipts vanish or a Land of Cockaigne allowing agents to spend what they did not earn is not allowed.

First generation CGE models—still widely in use—assume perfect competition and constant returns to scale (CRS) (Shoven and Whalley, 1992). Firms take prices as given and do their best to adjust to those prices. CRS means that any production plan fixing the goods to sell and goods and factors to buy for use in production can be scaled up or down ad libitum. This is the traditional assumption making life technically easy, but it is obviously special, ruling out economies of scale (EOS) that are prevalent in the real world and may alter the results emerging from shocking the economy substantially. We come back to EOS in Section “Economies of Scale.”

Under perfect competition and CRS there are only two possibilities for a firm to act in equilibrium. Either prices are such that the maximum attainable profit just equals zero and the firm produces at which activity level ever market demand requires it to produce, or the firm is unable to break even and shuts down. In both cases, there are no profit shares to be transmitted from firms to households. Note that zero profit does not mean zero capital income. Capital is a production factor owned by households, such as labor. Capital income is the revenue received from selling the factor to firms.

In general, firms can produce more than one kind of output good, and one kind of good can be produced by more than one firm. Different from classical input-output analysis, no one-to-one correspondence between industries and commodities is required. Households are always assumed not to have any influence on prices. They maximize utility subject to their respective budget constraint, taking all goods and factor prices as given. Finally, in equilibrium prices and activity levels must adjust in such a way that markets clear.

Considering a closed economy without trade and income flows with the rest of the world, and incorporating the state as well as investment demand into the household sector, we end up with the following system of equations and corresponding unknowns:

$$\sum_{f \in F} x_f I_{fi}(\mathbf{p}) - \sum_{f \in F} x_f S_{fi}(\mathbf{p}) + \sum_{h \in H} D_{hi}(\mathbf{p}) = 0 \text{ for all commodities } i; \text{ unknowns } \mathbf{p}$$

$$P_f \leq 0; \quad x_f \geq 0; \quad P_f x_f = 0 \text{ for all firms } f; \text{ unknowns } x_f$$

with profit per unit of activity:

$$P_f = \sum_{i \in C} p_i S_{fi}(\mathbf{p}) - \sum_{i \in C} p_i I_{fi}(\mathbf{p}).$$

The set of firms is denoted F . For each firm f in the set of firms one has to determine a level of activity x_f . The required input of commodity i in the set of commodities C per unit of activity, given the vector of all prices $\mathbf{p}$, is $I_{fi}(\mathbf{p})$. Thus, total input demand of the firm is $x_f I_{fi}(\mathbf{p})$. Similarly, $x_f S_{fi}(\mathbf{p})$ is the firm's output supply of commodity i . Remember that we allow for multiproduct firms. Finally, $D_{hi}(\mathbf{p})$ is net demand for commodity i of household h in the set of households H . Hence, the first equation says that total net demand must be zero for all commodities i ; in other words, markets must clear. The term "commodity" here also covers factors of production such as capital and labor, possibly differentiated by skill, location, and others. Note that demand and supply for commodity i do not just depend on the price for commodity i , but also on all prices gathered in the vector $\mathbf{p}$. Note furthermore that one cannot express demand and supply of firms as a function of prices alone because firms are willing to scale supply and demand up or down at will if prices are such that they just break even. Thus, levels of activity appear as additional unknowns to be determined by the second line, expressing not an equation but a so-called complementarity. In a somewhat tricky way, it just repeats what has been verbally already explained: profits must not be positive, but may allow or not allow the firm to break even. In the former case ($P = 0$), the level of activity can be positive or zero, in the latter ($P < 0$) the firm must shut down. We thus have just the right number of equations for the unknowns to be determined. One can show that one of the equations is redundant; it must automatically hold if all others hold due to the fact that all budget constraints are fulfilled (WALRAS' Law). This delivers one degree of freedom for introducing a further equation fixing a price level, but not shown here. The formal system must be modified, if a public sector raising taxes and paying subsidies enters the scene. The modifications are tedious to describe but straightforward. In any case, one must take care that taxes paid by private agents add up to the tax revenue of the public sector and that subsidies received by private agents add up to subsidy expenditures of the public sector.

This is a nonlinear complementarity system. Equations can be understood as a special case of complementarities. Conversely, a complementarity can be transformed into an equation, but unfortunately one that is non-differentiable even if all functions involved are differentiable. Therefore, complementarities are more difficult to solve, but there exist powerful algorithms now doing the job also for large systems.

Once all technologies and utility functions are specified by concrete functional forms (see Section "Functional Forms") one solves this system twice, once for the benchmark and once for the alternative, after a shock. The benchmark solution should replicate the relevant data, which is made sure by an appropriate choice of parameters. The difference between benchmark and alternative is the impact we are looking for.

Functional Forms

In a general equilibrium model agents are characterized by technologies or preferences that determine their respective responses to market prices. In the textbook version of the model these building blocks are typically specified in an abstract way by just requiring them to fulfill certain regularity conditions such as CRS, monotonicity, and convexity necessary to make the mathematical machinery of the theory work. For computation this is not enough. We need specific parametric functional forms that can be implemented on a computer.

Microeconomics tells us that the technology and thus the input and output choices of firms (the functions I_{if} and S_{if} in the equations in Section "The Structure of CGE Models") are completely determined by the firm's cost and revenue functions (the "dual approach"). The cost function specifies the minimal attainable input cost per unit of activity, given the input prices. Similarly, the revenue function specifies the maximal revenue per unit of activity, given the output prices. The expenditure function is the analogous concept for describing the preferences of households and thus the demand functions D_{ih} .

There is a whole bunch of functional forms for these functions proposed in the literature, ranging from LEONTIEF and COBB-DOUGLAS to more and more complex constructs with strange names, constant elasticity of substitution (CES), constant elasticity of transformation (CET), LES, CDES, addilog, translog, AIDS, and more. Criteria for choice are as follows:

- Theoretical consistency: A form should fulfill certain mathematical properties implied by optimization behavior. For example, a cost function must be linear homogeneous (proportional price changes lead to proportional cost changes), monotone, and concave.
- Factual conformity: A form should conform to stylized facts about agents' behavior. For example, representing consumer behavior by a COBB-DOUGLAS function does not—though widely applied—conform to the observation that the composition of

consumer demand systematically changes with changing incomes. This can be important in transport analysis, as rich people choose for example different modes of transport than poor people, facing identical prices.

- Flexibility: A form should be flexible enough to represent different patterns of behavior.

Choosing a functional form is a bit of an art. One has to trade off flexibility against parametric parsimony. More flexible forms need more parameters to tune them to observed behavior, but there is often little evidence to assign numbers to them. Many functional forms allow for a distinction between two types of parameters, shifters (or position parameters), and elasticities. Shifters are parameters used to trim the functions in such a way that accounting data are reproduced in a benchmark equilibrium. For example, for a cost function representing input choice one needs n free shift parameters for n inputs. Elasticities tell how agents respond to price changes. From a benchmark data set one cannot infer on these parameters. They must be borrowed from econometric studies in the literature. Fixing them is guesswork. Shakiness of the elasticities is a critical point in CGE analysis.

A convenient and most popular form for the input composition is the CES function. It implies that, for any pair of goods, the percentage response of the input ratio to a 1% change of the respective price ratio is a negative constant (the so-called elasticity of substitution) that is uniform across all pairs of goods. This form is parametrically parsimonious in that one needs, beyond shift parameters, only a single further parameter, the elasticity of substitution. Obviously, however, the function is rather inflexible, not allowing for low substitutability between certain pairs of inputs and high substitutability between others.

A higher flexibility is achieved by nesting CES functions, as in the trade example in Section “Spatial CGE and Transport.” High flexibility is achievable by complex multilevel nesting structures, but at the cost of large information requirements. Consumers’ choices can be dealt with in a similar way. An analogous concept can be applied for output choice of multiproduct firms, with the CET function. It has the same mathematical form as the CES function, with the negative elasticity of substitution replaced by the positive elasticity of transformation. While the input ratio falls with an increasing price ratio, the output ratio goes up.

Spatial CGE and Transport

Some early CGE studies on transport used simple single-region national CGE model. Here, transport is just another industry whose output, the transport service, is used by firms as a production input or by households as a consumer good. A shock may be a public infrastructure investment raising the transport sector’s productivity, a levy imposed on transport for damaging emissions, a tax, a technology improvement, and so on.

This is fine as long as one is only interested in the national scale, but the strength of the CGE approach becomes apparent in particular when it comes to the spatial dimension of transport policy. In the spatial dimension, transport is not just another industry, but a core explanatory factor for understanding the subject at hand.

Conceptually, there is not much difference between a single-region and a multiregional CGE, except for the definitions of agents and commodities. Agents are assigned to regions, and commodities are distinguished by their respective place of availability. A commodity at the place of production is understood as different from the same good, after it has been transferred from the place of production to the place of consumption. This transfer is regarded as another production process generating the commodity at the place of consumption using the commodity at the place of production and a transportation service as inputs.

The nesting concept is perfect for representing this transformation process, as illustrated for trade flows from several regions of origin to one destination in Fig. 1. For transferring a good from one of the origins to the destination, the good itself is combined with a transport service to obtain the same good at the destination. The transport service and the good are combined in a fixed proportion. In other words, the respective elasticity of substitution is zero (called LEONTIEF technology). On an upper level, goods of the same kind stemming from different origins are combined to obtain a composite further used in production and final consumption in the destination region. The elasticity of substitution is positive but finite, representing the willingness of customers to substitute sources in interregional trade as a response to relative price changes. Some authors borrowed estimates of this elasticity from international trade studies using a gravity model. As one is able to estimate trade costs in international trade, one can infer on this elasticity from the estimated trade cost elasticity of the gravity equation. The application of elasticities in international trade to interregional trade

Figure 1 Nesting structure for transport and trade. In the lower nest (to the left) the commodity and the transport service are combined in fixed proportion (LEONTIEF technology), in the upper nest (to the right) commodities from different origins at the destination are combined by a CES function with positive finite elasticity of substitution.

within nations is, however, a weakness of this approach. Short-distance elasticities may be larger because less trade cost sensitive goods select into international trade than into interregional trade.

Simulating a cost-reducing infrastructure improvement needs to shock the transport technology in such a way that transport services cost less per unit after the shock than before, given unchanged input prices of the transport service producer. This induces complex adjustments through the entire economy. If transport from some origin to some destination becomes cheaper, firms and households substitute goods from the cheaper source for goods from other sources. Producers at the origin sell more, while customers at the destination get their respective input or consumption bundle at a lower price per unit of the good composed of deliveries from all sources. At the end of the chain households at the destination will pay lower prices, while households at the origin will earn higher factor incomes. But not all households at the origin and destination gain. Some may suffer from higher prices at the origin without benefiting from higher factor income, and some may suffer at the destination from facing tougher competition by producers at the origin now enjoying easier market access. The strength of a CGE is to cover all these direct and indirect channels in a single consistent framework, preventing oversimplifying conclusion that takes some channels into account and neglecting others.

Obviously, with many regions and industries, the model design becomes rather complex. Economists have invented a dirty trick simplifying it considerably, the iceberg transport cost. It means that the resource used for transport is the delivered commodity itself, instead of a special transport service as explicated earlier. A certain percentage of the commodity is simply used up for doing the transport work. It melts like an iceberg. Let's say a transport engineering study (we come to that later) tells that the transport cost for getting certain goods from an origin to the destination amounts to 10% of the good's value. This is implemented by assuming that 10% of the quantity melts, while the price per unit at the destination exceeds the price at the origin by the factor of $1/0.9$, such that the values (price times quantity) at the origin and destination coincide. While sounding strange, this greatly simplifies model designs. As long as the issue at hand is just the impact of transport cost changes and not developments in the transport industry itself, the approach is not seriously misleading.

Some authors, discontent with taking over simple aggregate cost figures from engineering studies, try to extend the CGE framework to also incorporate the different logistic decision levels such as mode choice, route choice, urban parking, and more into a unified CGE, that is, a grand overall system of complementarities simultaneously solving for production, consumption, trade, mode choice, route choice, etc. This is an interesting direction of research from a methodological point of view, but applicability to practical policy studies is still limited. The technical requirements are formidable.

Leaving the within transport sector details to the well-established transport engineers' modeling strategies and establishing an interface between the transport model and the economic CGE model turned out to be a more powerful pragmatic strategy. Nevertheless, the interface raises subtle technical questions related to different modeling philosophies of CGE modelers and transport engineers. A striking symptom of this difference is the fact that CGE modelers love CES functions for choices, for example, region of origin choices in trade (see earlier), while transport engineers love random choice models, in particular the logit model. Though these two forms have been shown to be close relatives, the difference matters for project evaluation.

Let us take mode choice as a simple example. A CGE modeler measures the quantities of transport by each mode and the composite quantity generated by combining modes according to the LEONTIEF convention (see earlier): value divided by the arbitrary benchmark price for the reference case. Adding up values by mode gives the value of the composite. After a shock (cost reduction for one mode, say), both, quantities and prices, change, but value aggregation is kept; adding the after-shock values by mode yield the value of the composite. The change of the composite price measured by the cost function is the right evaluation measure for the cost decline of one of the modes. Quantity aggregation does not hold, in general. Adding up quantities by mode does not yield the quantity of the composite.

The transport engineer measures quantities by mode in tons. Adding up tons by mode yields tons of the composite in the benchmark as well as after a shock. Using a random choice model with random components added to prices, the correct evaluation measure of a cost reduction for one mode is the expected minimal expenditure including the random components, the logsum in case of a logit model. If this measure is inserted as price of the composite, value aggregation does not hold, in general. The accounting consistency of the CGE model gets lost. In practice, some authors used therefore simply the weighted average of mode costs as composite price. This keeps value aggregation but may give wrong answers in project evaluation: average costs can increase, if one mode (a particularly costly one) becomes cheaper and none more expensive. A heterogeneous agents approach may offer a way out of this dilemma (see briefly on that in Section "Further Extensions and Conclusion").

Economies of Scale

The traditional CGE approach assumes CRS and perfect competition. These assumptions clearly contradict the evidence; EOS are relevant in many industries. Excluding them by assumption can be very misleading in project evaluation. If average cost declines with output expansion, average cost exceeds marginal cost. If prices equal marginal costs, as implied by perfect competition, firms could not cover their costs. The theory collapses.

Let us look at two ways to cope with EOS, both easily applicable in a CGE. They may be regarded as the extreme ends of an entire continuum of model specifications. Superficially looking a bit at ad hoc, they both have deeper roots in modern microeconomics. The first approach is average cost pricing illustrated in Fig. 2. If a policy intervention shifts the demand curve to the right, output expands and average cost declines, and hence the price falls. This is welfare enhancing.

Figure 2 Response to market expansion, DIXIT-STIGLITZ version. Explanation of symbols: x = effective output; p = output price; ac = average cost; superscripts 0 and 1 denote equilibria before and after an expansion shock, respectively. The blue lines are demand schedules; the red curve is the average cost curve. Effective output includes the utility or productivity effect of increased diversity.

Simple as it is, the approach can nevertheless be derived from a popular model of monopolistic competition, the DIXIT-STIGLITZ model (Dixit and Stiglitz, 1977). According to this model, the industry output is a composite of many varieties of goods belonging to the respective industry. Producers of an individual variety have a certain degree of monopoly power to set a price above marginal cost. Entering the industry by offering an additional variety incurs a certain fixed cost, but otherwise it is free. Firms enter or leave the market until profits are driven to zero, that means until markups just cover the fixed cost. An expanding market induces market entry and thus an increase of product diversity. What is measured on the abscissa in Fig. 2 is effective output taking diversity into account. Moving to the right means more varieties, more of each variety, or a combination of both.

For implementing the model one does not need more than a single extra parameter, the elasticity of average cost with respect to industry output. It measures the percentage change of average cost per percentage change of output. In the DIXIT-STIGLITZ model this parameter is minus the inverse of the elasticity of substitution between varieties. If substitutability of varieties is low, the average cost curve declines steeply. Other justifications than the DIXIT-STIGLITZ model can also be put forward. But anyway, the mentioned elasticity is the only thing that matters empirically, whatever we accept as microeconomic background music.

At the other extreme of EOS models lies the oligopoly model illustrated in Fig. 3. As in the DIXIT-STIGLITZ model, average costs decline with an expansion of the market, but the price does not fall, as long as the marginal cost does not change (what is assumed in the figure for the sake of simplicity). Cost savings are entirely appropriated by shareholders of firms as additional profits.

A theoretical justification is the NEARY oligopoly model (Neary, 2003). As in the DIXIT-STIGLITZ model, industry output is a composite of many varieties, but in this case there is no entry or exit. The number of varieties is fixed. Each variety is the output of a tiny industry with a small number of firms interacting strategically within their respective tiny industry. They set a price according to the COURNOT oligopoly model. It depends only on the degree of substitutability between varieties and the number of firms in each tiny industry, both regarded as fixed parameters. Therefore, the price is a fixed markup over marginal cost. It does not respond to the market expansion.

To implement this approach, we also just need the elasticity of the average cost with respect to output as an extra parameter, the same information as for the former solution. In this case, this elasticity is not a constant, but we only need to know it for the benchmark. It is equal to minus the share of fixed cost in total cost. We also need the share of profits in the industry's turnover. This is available from the benchmark accounting data and thus no extra information to be taken from external sources. For both approaches, the equation system in Section "The Structure of CGE Models" needs to be modified, but we skip the technical details here.

Hence, for both approaches we need essentially the same extra information for calibration, and both lead to the same principal conclusion with regard to overall welfare effects of a demand shift: if an intervention lets the respective industry expand, this gives

Figure 3 Response to market expansion, NEARY version. Explanation of symbols: mc = marginal cost. For the other symbols, see Fig. 2. The dark gray rectangle is benchmark profit; the total gray rectangle (dark and light) is after-shock profit.

rise to an extra welfare gain that would not occur under CRS and perfect competition. The transport policy intervention can therefore generate a wider economic benefit due to sectoral shifts induced indirectly in the economy. This sword, however, cuts both ways; the contraction of the respective industry leads to a welfare loss.

While the two approaches lead to similar (though slightly differing) overall welfare effects of a demand shift, the distributional impact is completely different. In the first approach all gains are reaped by the customers, whereas in the second approach they go entirely to the shareholders of the firms. This implies that also the regional incidence can be quite different, because customers and shareholders reside at different locations. An in-between of the two approaches can be constructed by assuming that the price declines with market expansion, but less steeply than the unit cost. This requires another additional parameter.

Further Extensions and Conclusion

Many important aspects had to be omitted in this short review. One is dynamics. Transport policies affect private investments, inducing welfare changes in the future. To account for them in a consistent way, a dynamic approach is needed. The strict neoclassical concept of dynamics is a model with forward-looking agents. Unfortunately this is not only a mathematically demanding, but also a disputable concept. Few people would accept that agents have strong beliefs about future prices and quantities that later turn out to be correct, at least on average. What speaks in favor of the approach is that dispensing with it means to also dispense with neoclassical equilibrium as a guiding principle and to get lost in arbitrariness, when it comes to investment and saving. Most applications rely on more or less plausible approaches to specify saving and investment functions linking static equilibria for consecutive years. But this is disputable as well. In any case, the theoretical strength of the CGE machinery gets lost in a dynamic context.

A more promising extension is introducing agent heterogeneity that recently is an important theme in trade theory and has a longer tradition in urban CGE models. To make sure that not all households in a city react in the same way—in contradiction to the evidence—it is assumed that they belong to a large population of individuals with varying preferences drawn from a common distribution (Anas and Liu, 2007). This leads to the stochastic choice idea that transports planners and engineers adhere to already for long.

To summarize, CGE analysis is a theoretically well-founded assessment tool in transport policy appraisal, at least as long as we do not leave the firm ground of static models. CGE models are notorious for being complex and too expensive for practical application, but this is often due to the fact that one-fits-all models are asked for by policy-makers. It is highly recommended to design tailor-made models for specific questions—parsimonious with regard to the number of agents and markets—that can be calibrated with a small and easily accessible data set. The bad reputation comes from the bad habit to let models grow bigger and bigger, which makes them necessarily more and more expensive and less and less transparent.

Type of Study

Starting in the 1960s, the value of travel time (VTT) has been estimated empirically in an increasing number of studies. The latest meta-analysis on European evidence is based on 389 studies, and additional meta-analyses including data from the other parts of the world suggest that the total number of studies is at least 500 and likely much higher.

In this article, we focus on studies where the estimation of the VTT is the primary motivation for the study, with particular emphasis on national VTT studies. However, the VTT is also estimated explicitly or implicitly in other types of studies. **Table 1** summarizes some characteristics of typical study types.

Most studies that empirically elicit VTT are based on a similar general methodical approach, that is, to infer VTT from choice data using statistical inference—typically by means of logit models and maximum likelihood methods. The choice data can stem from stated choice (SC) experiments or/and from revealed choice (RC) data. The specific requirements for data and model specification in different studies are often motivated by the purpose of the study and the later application of VTT.

Table 1 Overview over some type of studies that estimate VTT

<i>(Some) types of project estimating VTT</i>	<i>National VTT studies</i>	<i>Other WTP studies</i>	<i>Mode choice models for transport planning</i>	<i>Consultants projects for industry</i>	<i>Academic studies</i>
Typical funding/ interest group	Transport authorities or Ministry of Finance	Various	Transport planners	Transport operators, stakeholders	Academia
General purpose	Project appraisal	Primary focus on other WTP values	Predicting travel demand	Eliciting travelers WTP and/or choice probabilities	Scientific/ methodological
Role of VTT	Primary parameter of interest	Various, may be included primary to control other WTP for VTT	Marginal rate of substitution between travel costs and time	Typically, one of many estimated parameters	Various
Typical application of VTT	As unit values for national CBA handbooks	Various	Remain implicit in utility functions underlying transport model	Optimization of prices schemes and timetables	None
Typical segmentation of VTT	Trip element, travel mode trip purpose, trip distance	Various	Trip purpose, time coefficient may be travel-mode-specific	Various, including user groups and geography	Various
Requirement for representativeness	Very important, should apply for the whole nation	Various	Less important due to possibility to recalibrate model	For specific corridors/markets	Less important (more focus on internal validity than external)
Typical data type	Stated route choice	Stated choice and other SP including CV	Revealed mode choice	Route and/or mode choice (often SC)	Various, including combined SC/RC
Typical estimation model	Mixed logit model in WTP space	Various	Nested logit model	Typically, simpler model (MNL)	Often mixed logit or other state-of-the-art

CBA, Cost–benefit analysis; *CV*, continuous valuation; *MNL*, multinomial logit model; *MXL*, mixed logit model; *RC*, revealed choice; *SC*, stated choice; *VTT*, value of travel time; *WTP*, willingness-to-pay.

Data and Estimation Approach in National VTT Studies

As stated in **Table 1**, national VTT studies are conducted with the purpose to provide unit values for cost–benefit analysis (CBA). This implies that the obtained values should be representative for the whole traveling population and relevant for (long-term) welfare analysis. It is worth mentioning that the VTT, that is relevant for welfare analysis, is not necessarily identical to the VTT, which is most relevant for predicting behavior, in particular short-term behavior.

Overview Over National Studies

The 1987 UK study was the first national VTT study of its kind. Relying on SC data and showing that the VTT can be estimated with sufficient statistical accuracy without the use of RC data, the study set the standard for national studies conducted in the 1990s. This first wave of VTT studies was completed in Europe, with the notable exception being the national VTT study of New Zealand in 1999.

In the new millennia, seven countries in Europe conducted (at least) one national VTT study (see **Table 2** for an overview). While there seems to be plenty of empirical evidence on the VTT over the whole world (e.g., there are conference papers reporting on meta-analysis based on 25 VTT studies from Africa and, another one, based on 216 VTT values from Japan), we are not aware of studies outside of Europe after year 2000 that would be characterized as national studies. This relates to the fact that CBA has a stronger tradition and is more frequently done in Europe than in the rest of the world. In some countries, such as France, the official unit value recommendations for VTT in CBA handbooks are inferred from several (minor) VTT studies, rather than one large-scale national study.

From a methodical point of view, the 2004 Danish study, in particular the work on data modeling and estimation by Mogens Fosgerau and colleagues, was very influential on consecutive studies in Sweden, Norway, and the Netherlands. These studies relied on choice experiments (CEs) with time and cost as the only attributes to estimate VTT in main transport mode [while VTT for other time components, like access- or waiting time, and other willingness-to-pay (WTP) values were derived from additional CEs with more attributes]. This so-called 2-attribute choice experiment (2aCE) received some critique over the years (see discussion later), but remains a major part of the experimental design in the 2014 UK and the 2018 Norwegian study. In the former study, the data from the 2aCE were combined with multi-attribute CEs for a pooled data estimation of VTT. Estimation based on multiple and more complex CEs is even more characteristic for the 2012-German study that used different CEs, including mode choice, route choice, and (long-term) residential/work place choice with up to 14 attributes per CE, to estimate VTT.

The German study is also prominent in the inclusion of RC data in the modeling work for VTT departing from earlier practice in national studies that relied solely on SC data.

Choice Experiments

The design of CEs is a crucial part of SC-based estimation of VTT. As indicated in **Table 2**, most (national) VTT studies apply route CEs. Mode CEs are less common likely because of the risk that the alternative-specific constants are confounded with the alternative-specific time coefficients underlying VTT.

To mitigate the general challenges of the hypothetical nature in stated preference studies, CEs should be designed such that choices are perceived as realistic by the respondents. There are two main approaches to try to achieve this:

1. The choice situation is framed around a reference trip that the respondent recently made. In the choice tasks, the respondent is asked to think back at the reference trip and to imagine that some (few) attributes have changed while all other travel conditions remain as in the reference trip.
2. One includes all relevant attributes (typically more than 5 attributes) in the CEs and varies them across alternatives.

(1) sets higher demands on abstraction (and imagination) on the respondents, while (2) requires higher cognitive abilities from the respondents due to the need to process many attributes and numbers.

Within type (1), we can further distinguish between those CEs with just 2 attributes, travel time, and cost (the aforementioned 2aCE) and those with more attributes (typically 3–5 attributes). **Fig. 1** shows typical examples of CEs with different number of attributes.

Besides choosing the number of attributes, a realistic and meaningful design and framing of attribute values and attribute combination is important. In the 2aCE, one alternative is typically faster but more expensive (while the other is cheaper but slower). In countries that have no road tolls, this setup may be viewed as unrealistic for car travel. Another challenge with the 2aCE might be that respondents understand that they are asked to reveal their WTP, which is likely to increase the likelihood that respondents answer strategically (i.e., not revealing their true preferences). This challenge might also apply for CE with more attributes, but there the trade-off between cost and time is more concealed.

The complexity of the underlying statistical design increases with the number of attributes. However, there are standard methods and tools to create statistical designs, both orthogonal ones where there is (close to) no correlation between attribute values and efficient designs that include an intentional correlation between attributes based on a priori expectation of parameter values.

Typical example of 2-attribute choice experiment		Option A	Option B
	One-way fuel costs	20.30 €	27.50 €
	One-way travel time by car	2 h 23 min	1 h 55 min
		☐ Option A	☐ Option B
Example of a choice experiment with 4 attributes (<i>attributes taken from the UK study; value, format, and layout adjusted by the authors</i>)		Option A	Option B
	One-way fuel costs	22.40 €	24.50 €
	Traffic conditions	1 h 22 min in heavy traffic 55 min in light traffic 23 min in free flowing traffic	22 min in heavy traffic 1 h 55 min in light traffic 58 min in free flowing traffic
		☐ Option A	☐ Option B
Example of a choice experiment with many attributes (<i>attributes taken from the German study; values, format, and layout adjusted by the authors</i>)		Option A	Option B
	Departure time	08:03 am	08:40 am
	Expected travel time of which driving of which in heavy traffic of which walking to/from car	1 h 22 min 1 h 2 min 15 min 5 min	1 h 42 min 55 min 40 min 7 min
	Expected arrival time	09:25 am (in 85% of cases) 09:00 am (in 5% of cases) 09:55 am (in 10% of cases)	10:22 am (in 50% of cases) 10:00 am (in 20% of cases) 11:05 am (in 30% of cases)
	Travel costs	23.40 €	21.50 €
		☐ Option A	☐ Option B

Figure 1 Examples of choice experiments.

Independent of the number of attributes, it is considered standard practice to pivot attribute values around reported reference values. In the 2aCE, the reference values of cost and time typically always occur in one of the two alternatives, but not always in the same alternative. This increases realism and makes it possible to test for reference-dependency [see Section “The Absolute Size of the Time Saving (Size Effect)”].

In the 2aCE, the trade-off between cost and time is “unpolluted” by other attributes, which comes at the advantage of better control about the effective range of trade-offs (bids) in the design. This may make it easier to design the CE such that one observes the whole VTT distribution.

Estimation Models

The VTT is commonly estimated based on parametric models. Nonparametric models, which are only practically feasible with the 2aCE, are sometimes used to test if the bid range in the CE design is appropriate, typically based on pilot data. In order to understand variations in VTT and in order to be able to control for certain effects prior to the inference of mean VTT values, parametric models are needed.

The state of the art of estimation models for SC data depends on the type of CE.

For the 2aCE, the so-called integrated approach to VTT estimation, introduced by the Danish national study, is the most commonly applied model. It departs from a decision rule that is verbally formulated as: “A respondent chooses the faster/more expansive alternative if his/her true VTT is larger than the offered bid.” As the subjective true VTT is not observable to the researcher, an IID logistic distributed error term ε_{nj} for respondent n and choice task t is introduced. The error term is scaled by the homogeneity parameter μ .

$$y_{nt} = 1 \text{ iff } \log VTT_{nt} + \frac{1}{\mu} \varepsilon_{nt} > \log V_{nt} \quad (1)$$

where $V_{nt} = \frac{|\Delta C_{nt}|}{|\Delta T_{nt}|}$ is the trade-off between the difference in the cost attribute and the time attribute, that is, the price to be paid for a unit of time saving.

The VTT is typically log-transformed and parameterized with covariates (A) and an additional error term (u_n) being constant for all choice tasks for a given respondent but being randomly distributed across of respondents.

$$\log VTT_{nt} = \beta_0 + \beta' X_{nt} + u_n \quad (2)$$

The beta-parameters and the variance of u_n (the mean value is captured by a constant term β_0) can be estimated with a standard mixed logit model for panel data. The distributional assumption of u_n (and thus of VTT) is a crucial assumption that can have strong effects of the inferred mean values. One can add semi-nonparametric (SNP) terms in the model that adjust the parametric distribution to the one that is nonparametrically observed.

Typical covariates in the X -vector include income, trip distance, dummies for trip purposes, and design variables, including dummies for recruitment (given mixed data collections, see Section “Recruitment Effects”), ΔT_{nt} [the “size effect,” see Section “The Absolute Size of the Time Saving (Size Effect)”] and dummies capturing the direction of the changes in cost or time relative to the reference value [the “sign effect”, see Section “Reference Dependency (Sign Effect)”]. The direct modeling of the effect of covariates on VTT, sometimes referred as modeling in the marginal-rate-of-substitution (MRS) space, makes the interpretation of beta-parameters straightforward. It is also technically easy to simulate the VTT distributions given (2) based on beta-parameters, the observed vector X and Monto Carlo draws of u_n . One can also change the X -vector based on input data from other sources or weight single observations such to obtain a more representative distribution.

For CEs with more than 2 attributes (or alternatives), the integrated approach is not feasible and model formulation must be done in utility space, where the VTT is derived as the ratio between the time and the cost parameter. It is, however, possible to rescale the utility (typically by factoring out the cost coefficient) such that the scale can be interpret in monetary term. The rescaled time coefficient (interpreted as VTT) can then also be parameterized with covariates. The 2014 UK study also suggested ways to account for size and sign effect on VTT (see later) in multiple-attribute CE. However, the required modeling work is more involved and results are more difficult to interpret compared to the integrated approach.

As mentioned earlier, the UK and the German VTT study also build estimation models on pooled data from different CEs. An important feature of these models is to allow for different utility scales (error variances) from data from different CEs.

With the 2aCE, one estimates the VTT that corresponds implicitly to the average travel quality or comfort experienced by travelers on the reference trip. To capture the effect of quality on VTT, one will need additional CEs in which the quality is presented and varies exogenously. However, the VTT from the 2aCE is not necessary the same as in multiple-attribute CE, such that inconsistency may arise. This is a disadvantage with the 2aCE compared to more complex CE and/or modeling approaches based on joint estimation.

Selected Challenges

The Absolute Size of the Time Saving (Size Effect)

A typical empirical finding is that WTP increases over-proportionally with the size of the time saving (one time saving of 20 min is more valuable than 2 time savings of 10 min) implying that the VTT increases with the absolute size of the time saving. This is obviously a challenge to the concept of unit values applied in CBA.

While this size effect is likely to reflect patterns of true preferences, and therefore may also be an issue in modeling based on RC data, the size effect is of particular concern in SC-based estimation. This is because the absolute size of the time saving (ΔT) is chosen by the researcher through the statistical design, which means that VTT results are sensitive to the SC design.

The best practice is to estimate the effect of ΔT and to simulate the VTT distribution for a predefined value of ΔT . In this case, the results get at least reproducible.

Some researchers have additionally argued that SC choices with very small time savings (i.e., ΔT of a few minutes) are unreliable; this has led to the practice adopted in many VTT studies to set a requirement on the trip duration (e.g., at least 10 min) for the reference trip. Regarding the merits of small time savings one may distinguish between internal and external validity. It might be that small time saving helps to identify the correct function relationship between VTT and ΔT in the SC-choice context, that is, in a short-term perspective, but that small time savings are not valid for long-term welfare analysis. A pervasive argument for the latter is that respondents are unable to recognize longer-term advantages of short time savings (e.g., the possibility of rescheduling activities).

Reference Dependency (Sign Effect)

Even more so than the size effect (see previous section), reference dependency (the sign effect) is a core conflict between behavioral economics and welfare economics. Behavioral economics suggest that people value the amount of goods not absolute, but relative to some internal reference value. Empirical evidence largely supports this theory and point to loss aversion, that is, that respondents value losses (negative changes compared to the reference point) stronger than gains. For the VTT, this implies that the WTP to improve travel time relative to the reference value is lower than the monetary compensation one requires to accept slower travel times (referred to as willingness-to-accept, WTA).

For welfare economics, it is problematic that the VTT is lower in WTP situations compared to WTA situations. For the estimation of VTT that is to be applied in CBA, it is therefore common practice to calculate a “reference-free” VTT. A way to achieve this is to include marginal effects for the sign of change in the cost and time attribute in the parameterization of VTT [e.g., the X -vector in Eq. (2)]. This transforms the systematic utility in value functions that can exhibit loss aversion. Parameters for the sign variables are estimated but then removed for the simulation of VTT distributions and calculation of mean VTT.

It is likely that the sign effect is amplified in SC, and in particular in pivoted CE where respondents are framed to a reference trips prior to the CEs. This makes the reference values for the time and cost explicit and easily recognizable in the choice cards, especially in the 2aCE where reference values are typically two of the four presented values.

Mode and User Type Effects

Estimating the VTT from route CEs that are based on reference trips, one infers VTT unit values that relate the current user group of the given transport mode (the VTT in bus for bus users or the VTT in train for train users). This makes it impossible to distinguish between mode effect that stems from the comfort level of travel models and the user type effect that stems from differences in opportunity cost of time (OCT) across user groups.

To disentangle the two effects one can ask respondents to answer CEs also for an alternative mode. This gives choice data for various travel mode/user group combinations. The marginal effects of this combination on the VTT can be estimated in a joint model by the inclusion of dummy variables in the X -vector in Eq. (2) in the case of the 2aCE.

It is then possible to simulate the mean VTT in different travel modes for any user group, including the “average” user group of all travel modes. (In practice, this requires some assumptions on how to weight the impact of different current user groups into the “average” user group.) This approach is adopted in the 2018 Norwegian Valuation study. It can be motivated by removing inconsistency in the VTT when considering transport projects that make travelers switch transport modes and by equity consideration for welfare analysis.

How to treat equity issues for welfare analysis is debated in the literature. The most radical practical approach is to use a generic value for all user groups and transport mode. However, this will come at the cost of lower precision.

Estimating VTT for Business Trip

The value of business travel time (VBTT) is different from the VTT for other purposes as it entails not only the private valuation of the traveler but also the employer’s valuation of time savings.

Most studies rely on (various variants of) the so-called Hensher formula that takes into account (relative) onboard work productivity (higher productive reduces the loss in the marginal product of labor) and the employee’s valuation of time savings. The former may be derived from different survey questions given that respondents are able and willing to self-report relative productivity. The latter can in principle be estimated from CE; however, the framing and interpretation of the cost attribute can be a challenge, as the employee is typically not paying for business trip for himself/herself.

Estimating VTT for Cycling (and Walking) for Transportation

As there are no out-of-pocket costs for using cycle, there is a challenge regarding the payment vehicle in valuation methods, that is, the cost attribute in CE. The typical approach is to use a mode choice setting where the marginal utility of money is inferred through the cost attribute of the paid-mode alternatives.

The VTT in cycle is likely to depend on the cycling infrastructure due to different levels of safety and cycling comfort. To avoid potential double counting in appraisal where safety improvements enter as a separated post in CBA, one would like to estimate the VTT in cycle as controlled for safety. This is most rigorously done when accident risk enters the CE as an independent attribute.

The VTT may also depend on the degree to which health effects of cycling are internalized by cyclists (the VTT becomes lower if travelers take the benefit of health into account). Isolating the health effects from the VTT is a recognized but methodologically not yet resolved challenge.

The mentioned challenges also apply to the VTT of walking for transportation.

Recruitment Effects

As mentioned in Table 1, representativeness is very important for national VTT studies. A central question is therefore how to recruit a sample of respondents that is most representative for the general travel population.

VTT-related questionnaires are typically involved and take some time to complete, typically between 10 and 25 min. A strong concern is that those that do not mind spending time answering a survey have a low OCT in general, which implies a low VTT. This sample selection bias is not rigorously testable as unobserved characteristics are likely to be main drivers behind the effect.

Empirical results from the latest Dutch and Norwegian VTT studies point to that members of internet panel have lower VTT than nonmembers, also after controlling of observables such as age and income. It is suggested that recruitment in field leads to a better representativeness compared to recruitment through internet panels.

Estimation With Revealed Preference Data

Having the multiple challenges of SC-based estimation in mind, it may surprise the reader why not more studies rely on revealed preference data when estimating VTT.

A principal challenge for the setup of the RC-based estimation model is that choice sets are not directly observed. Typically, the researcher has to assume which (other) alternatives the traveler considered and have to gather data on attributes for those alternatives from external data sources (e.g., network models). The inferred attribute values may be imprecise and/or not representative for attributes perceived by the traveler. In addition, RC is made in an uncontrolled environment, and many unobserved factors (attributes) may influence the RC.

For parameter inference, the main challenge with RC data is little variation and/or high correlation in attributes and explanatory variables. For example, for car trips and—to a lesser degree—for public transport trips, there is a very high correlation between travel cost and travel distance (and thereby travel time). This can result in statistically imprecise estimation and/or lead to that VTT estimates strongly vary with model specifications chosen by the researcher.

Traditionally, general data availability of RC data was an issue. With traditional travel survey data, for instance, the researcher observes only one (or a few) RC per respondent making parameter inference based on panel-data estimation techniques infeasible (or difficult).

The event of large-scale GPS/mobile data (possible combined with other “big data” sources), which is becoming more and more available for transportation research, may give new possibilities regarding the amount and quality of RC data. It may also be expected that advances in analyzing tools and techniques (e.g., artificial intelligent/neural networks) may help to define choice sets and infer parameters in large and complex RC data sets.

General Context

The high share of car transport in OECD countries and its projected growing share in non-OECD countries is a reflection of the quality of the service, this mode offers in terms of door-to-door service, comfort, and flexibility. It also follows from the policy context in terms of prices, regulation, infrastructure provision, land use policies, etc. While car transport offers substantial benefits to its users and contributes to the smooth functioning of the economy, it nevertheless also generates costs to other transport users and society in general. The same is true for other passenger transport modes, but the level and composition of these costs differs across modes.

Travel choices involve many dimensions: the decision to own a car or not, or to become a member of a car sharing scheme or not, the choice of the car type, the decision how much to travel, where to travel to, by which mode, by which route, at what time. In all of these choices people take into account the costs and benefits to themselves. However, generally they only consider the costs to other transport users and society at large to the extent that they are confronted with them by government policies. Those other costs concern mainly congestion costs, accident costs, and environmental costs related to air pollution, greenhouse gas emissions, and noise. On the other hand, when people travel actively (by walking or cycling) they may also generate social benefits through the positive impacts on their health, to the extent they did not yet take this into account when deciding to walk or cycle. The costs and benefits that are not taken into account are referred to as external. Because of their presence the transport choices that people make are not optimal in the absence of appropriate policies: they travel too much, the modal share of the car is too high, they travel too much in the peak period, etc.

In the presence of externalities, government intervention is justified. Governments can make use of several instruments to mitigate the problems associated with transport. Among the pure transport policies, the following main categories can be distinguished: pricing, regulation, public transport supply, and infrastructure policy. Pricing refers to economic instruments such as road pricing, fuel taxation, subsidies to public transport, taxes on car registration or car ownership, insurance pricing, etc. Examples of regulatory measures include safety, emission or fuel efficiency standards for cars, access regulations to certain areas, speed limits, etc. Public transport supply concerns the type, frequency and capacity of public transport services. Infrastructure policy refers to the capacity of the infrastructure. Moreover, transport decisions are affected by policies in other domains such as land use planning or energy policy. These various policy categories can all contribute to ensuring that the full potential of transport is truly exploited while keeping its negative impacts under control. The rules for determining good policy interventions have been the topic of many analyses and are described in various other chapters of this Encyclopedia.

This chapter focuses on pricing policies for car transport. The first section points out that there is still a gap between the current pricing policies and the recommendations from transport economic theory. Second, it is explored how this gap might be affected by a number of future evolutions and what this implies for the role of pricing policies.

Inherent to future outlooks, there are still many uncertainties about relevant future evolutions as well as their impacts. This chapter should therefore be seen as exploratory. Five categories of future evolutions are considered: (1) economic and demographic changes, (2) the further increase in the fuel efficiency of cars and the growing importance of alternative technologies, (3) the role of shared mobility and of (4) innovations in connected and automated mobility and (5) developments in pricing technologies. This list is not exhaustive, but is meant to cover different aspects: changes in mobility behavior, business models, technologies and regulatory frameworks. While those various evolutions can be expected to interact, this chapter tries to distill the impacts they might have individually.

The discussion considers the range of objectives that governments want to achieve with transport policies: correcting for the externalities, as well as raising revenue, while also taking into account distributional issues. Depending on the political preferences in countries, as well as differences in external costs, the relative importance of these objectives differs from country to

country and so does their scope. For example in the case of the revenue raising objective, transport taxes and charges may serve to finance particular infrastructure or may be earmarked to spending in the transport sector, but may also serve to raise money for the general government budget.

Current Taxation of Car Use

Currently, the tax instruments for car transport that are used most are fuel taxes and taxes on vehicle registration and/or ownership. In its overview of energy taxation in 2015 in 42 countries, covering almost 80% of world energy use, the [OECD \(2018a\)](#) finds that for road transport 97% of CO₂ emissions are subject to a fuel tax (excise tax and/or carbon tax), and that respectively 50% and 47% was taxed at an effective rate of more than 30 and 50 euro per ton of CO₂. Moreover, if in addition to the excise tax and carbon tax a value added tax applies, the effective tax rate on carbon emissions is even higher. In countries with low fuel taxes, an increase in these taxes that is also in line with the carbon content of the fuels would be an efficient way to reduce carbon emissions.

In addition, most OECD countries have taxes on the purchase and registration of vehicles, as well as periodic taxes related to the ownership and use of the vehicles ([OECD, 2018b](#)). In combination with the fuel taxes, these taxes generate substantial government revenues. The purchase taxes and periodic taxes are commonly differentiated in terms of vehicle characteristics, weight, engine power, age, cylinder capacity, type of fuel or electric propulsion, emission, or fuel efficiency standard, etc. While in the past the differentiation was mainly done with efficient revenue raising and equity purposes in mind, in the last decades environmental objectives have been integrated as well.

Fuel taxes are able to directly address the CO₂ emissions that are related to fuel consumption. However, for a given fuel category they cannot make a distinction between more and less polluting vehicles for non-greenhouse gas emissions. Moreover, if countries have different ambitions regarding the reduction of CO₂ emissions, fuel tourism and tax competition complicate the matter ([Mayeres, 2003](#)). Vehicle taxes can play a role there since they can be differentiated according to the emission characteristics of the vehicles. Purchase taxes/subsidies have an immediate effect when people buy a vehicle, but in the case of taxes, the prospect of having to pay these taxes may also encourage people to hold on to their older (more polluting and less fuel efficient) vehicles longer. Periodic vehicle taxes may therefore be more efficient to lead people toward cleaner vehicles, in combination with fuel taxes.

Additional tax policies that have an impact on car use are the fiscal treatment of commuting costs and of travel for private purposes using a company car. A favorable tax treatment of commuting expenses may however lead to longer commuting distances, and may affect as well modal choice, depending on the modes that are covered by it. In countries where the private use of company cars is under taxed this may lead to social costs in various ways, depending also on the fiscal rules that apply: by leading to more and more expensive cars, by increasing the car kilometers traveled and therefore the associated external costs, and by leading to a loss in government revenues.

Many cities in the world but also interurban corridors face considerable congestion problems, as is illustrated for example by the INRIX Global Traffic Scorecard indicator that is published annually. Fuel taxes are only an imperfect instrument to tackle congestion. A pricing system that is able to differentiate prices according to the location and time of day is preferable in this case ([Anas and Lindsey, 2011](#); [Mayeres, 2003](#)). Currently, there are not many examples yet of such road pricing systems. There are a still limited number of cities that have implemented road pricing, using cordon tolls or area licensing schemes (e.g., Singapore, London, Milan, Stockholm, Gothenburg, . . .). On some corridors high occupancy toll lanes are implemented, mainly in the United States but also in some other countries. There are also some examples of cities or countries that have explored road pricing, but where plans were halted in the end (e.g., the United Kingdom, the Netherlands). Other examples of road pricing for cars apply for specific infrastructures such as bridges, tunnels, or stretches of roads but are geared towards revenue rising rather than tackling congestion.

Exploring the Implications of Future Evolutions for the Taxation of Car Use

Demographic and Economic Growth

If population grows so will, *ceteris paribus*, mobility demand. In addition, the evolution of mobility demand will depend on the age and gender structure of the population. The global population is still expected to grow in the future, though at slower rates than before. A large part of this growth is projected to take place in urban areas, thereby increasing the challenges related to urban mobility. For evaluating the impact of these changes on transport demand, one has to be careful not to project the mobility patterns of the past to the future. Indeed the mobility pattern of age classes and men/women also changes over time. For example older people now have a higher mobility demand than older people in the past. Women now also have different mobility patterns than in the past. The demographic changes are taking place together with economic changes.

Mobility demand is positively related to economic growth, *ceteris paribus*. Economic growth leads to more freight transport demand. In situations with higher economic growth, there generally is more employment and higher income, both leading to higher mobility demand. Due to better infrastructure the possibilities to travel farther are also larger. As a result of all of these evolutions the 2017 Transport Outlook of the International Transport Forum ([OECD/ITF, 2017](#)) projects a substantial increase in road transportation worldwide, especially in non-OECD countries. The main driver is said to be the economic development. The baseline scenario of the outlook, which does not yet consider a possible uptake of new mobility services and which assumes a moderate increase in oil prices, projects a doubling of the annual mileage per capita for domestic non-urban transport in non-OECD countries between 2015

and 2050, while in OECD countries this would only change marginally. Urban mobility would be almost 95% higher in 2050 than in 2015, with the increase being concentrated mostly in non-OECD countries. All of this points to a growing need for policies that can mitigate or reduce the negative impacts of this larger transport demand, with a role to play for the different policy categories, including not only pricing but also the other categories mentioned above.

The economic development also implies, *ceteris paribus*, a higher value of travel time and of the other external costs, given the positive income elasticity of these valuations. Still, there might also be evolutions with opposite effects, as discussed in the section on connected and automated mobility. In case of the health and nature impacts of transport emissions, scientific knowledge can also be expected to evolve further, potentially leading to higher valuations of the external costs.

Fuel Efficiency and Electric Vehicles

Future carbon emissions by transport depend on the evolution of mobility demand on the one hand and the evolution of fuel efficiency and the uptake of alternative vehicles and fuels on the other hand. A global overview for 2017 by the International Council on Clean Transportation (Yang and Bandivadeka, 2017) shows that markets covering together slightly less than 80% of passenger vehicle sales (Brazil, Canada, China, EU, India, Japan, Mexico, Saudi Arabia, South Korea, and the United States) have in place regulations concerning the fuel efficiency or greenhouse gas emissions of cars. Three other major markets were planning regulations at that time (Australia, Thailand, Vietnam).

It should be noted that literature has pointed out such fuel efficiency or emission standards should be used with care because they can lead to smaller welfare gains than pricing policies (Parry et al., 2014). Still, they can have a role if fuel taxes cannot be set optimally, or in the presence of misperception market failures. For the latter aspect a recent empirical study however points out that car buyers to a large extent figure in future energy savings in their purchase decisions (Grigolon et al., 2018). Another reason for using standards is that they encourage research and development in innovative technologies that take a long time to develop as they offer the possibility to create a more certain long-term policy framework than pricing policies that can be changed more easily.

The further tightening over time of these standards that is in place or being proposed for road transport is expected to have a significant effect on future global oil consumption by the sector on condition that the necessary compliance and enforcement framework is put in place. Without higher fuel efficiency and without the uptake of alternative fuels and vehicles the 2018 World Energy Outlook of the International Energy Agency projects oil demand by the road transport sector to increase by 68% between 2017 and 2040 (OECD/IEA, 2018). However, if account is taken of future improvements in fuel efficiency, the growing use of alternative fuels and natural gas and the larger uptake of electric vehicles, the increase is limited to about 10%. This lower growth in oil demand is realized to a large extent by stricter fuel efficiency and emission standards and by improvements in engines and hybrid technologies: this brings down the increase from 68% to 32%. Electric vehicles lead to a further reduction by 12% points and the rest is realized by using more alternative fuels and natural gas.

Fuel efficiency standards and commonly used policies to promote the uptake of electric vehicles such as purchase subsidies, or benefits in the form of reduced charges for parking or the allowance to use bus lanes, lead to a reduction in the variable costs of road use. *Ceteris paribus*, this can be expected to lead to a rebound effect leading to an increase in road transport demand. Because of that part of the emission reductions will be offset and the other external costs of transport that are related to transport volume are also exacerbated. This implies that road pricing will have to play a larger role in order to tackle the remaining externalities. In that case the same principles of road pricing should apply to all vehicle types (i.e., also for electric vehicles), though the actual tariffs might of course differ in terms of the external costs they create.

Another consideration is that, at present, fuel taxes are an important source of government revenue. Also in some countries the income from the fuel taxes is earmarked specifically to finance transport purposes. With improved fuel efficiency and more electric vehicles for which energy taxes are typically low, this implies that alternative sources of funding have to be explored. Road pricing then also comes more prominently in the picture as a revenue raising instrument. An example of the awareness of these implications is found in a number of US states, where there is a growing interest in mileage based user fees, as a result of the projected fall in fuel tax revenues and high financing needs for maintaining and upgrading roads.

From the public economics literature it is known that in a second-best setting in which the government has to use distortionary taxes, the optimal tax on car use deviates from the Pigouvian tax. It then consists of both revenue raising component as well as a component that corrects for any externalities that arise, with both components incorporating distributional considerations.

Shared Mobility

While car travel by a privately owned car is still dominant now in developing countries and is also expected to become more important in developing countries, developments in ICT are leading to changing concepts of mobility, including options for shared mobility. Shared mobility covers a wide range of services: better options for organizing carpooling, new options for sharing rather than owning vehicles, on-demand ride services and micro-transit. The concept also refers to the availability of apps that enable and integrate the use of these transport services. These concepts can be briefly described as follows: (Franckx and Mayeres, 2015):

- With vehicle sharing members have short-term access to vehicles. Systems exist for cars but also other vehicles such as (electric) bicycles or electric kick-scooters. These vehicles can either be available at fixed stations or free-floating. The vehicles are often owned by companies, but for cars also peer-to-peer systems exist.

- With ridesharing, or carpooling, people who want to travel together are matched with each other, with the system functioning on a non-profit basis.
- In the case of on-demand ride services Transport Network Companies (TNCs) supply apps that in real-time bring into contact passengers with drivers and determine the price of travel. They can also offer ride-splitting, where passengers share a ride with someone else.
- Micro-transit is a form of demand responsive transit that serves a market segment between that of public transport and on-demand ride services. In this system transport services are supplied by minibuses with flexible routing and/or scheduling.
- Mobility-as-a-Service (MaaS): While car travel by a privately owned car is still dominant now, the idea behind MaaS is to supply comparable travel options, in which car ownership is no longer the starting point. The travel options are designed to meet the specific travel demand of the transport users, using different combinations of modes. All information on services and prices is available in the on-line platform of a mobility broker, where the transport services can be booked and the payment can be done. Depending on the system, individual solutions for transport can be combined (or not) with public transport services.

To the extent that the shared mobility services lead to lower transport demand, to a shift to more sustainable modes or to more environmentally friendly vehicles, they may reduce the external costs of transport and therefore the need for corrective pricing. Whether that is the case and to what extent is still to be fully understood. That is because these systems are still in full development and the behavior of the early adopters cannot be generalized to the wider group of transport users. Nevertheless, one can identify several mechanisms through which shared mobility may have an impact on the external costs of transport.

With car sharing and on-ride demand services prospective transport users are confronted with the costs of their trips each time they book a trip. In addition, with car sharing it takes more effort to use a shared car than a privately owned car: the car has to be reserved, one should walk or cycle to the place where it is parked, it should be brought back in time for the next user, etc. All of this may lead to less car km by the individual car user. Moreover, by providing a solution for the transport to and from public transport stations, car sharing or on-demand ride services can increase the modal share of public transport for longer trips; this argument also holds for other shared mobility systems that improve the first and last mile transport options (shared bicycles, kick-scooters). Ridesharing and ride-splitting reduce vehicle km by increasing the occupancy rate of the vehicles. In all of these cases it should be noted however that, if prices are not correct, a reduction in car km by some car users, leading to less congestion, may encourage other people who were previously discouraged to use their car to switch to their car again. So the case for road pricing in areas with congestion remains, though the optimal road prices may be affected.

With car sharing there is an additional advantage of the possibility to “right-size” the car, which increases the average energy efficiency. The fact that the shared cars are used more intensively than privately owned cars also leads to a quicker replacement and hence newer (less polluting) cars. There are also synergies with electric vehicles, as these are more interesting with higher annual mileage, resulting from many shorter trips in areas that have a high density of charging points. This is a market segment that can be served well by car sharing. Other synergies, with automated electric vehicles, may also exist, as discussed in the next section. It is also pointed out sometimes that if the companies supplying the car services are more sensitive to fuel costs than households, then the fuel efficiency of the shared cars could be larger. However, recent empirical evidence suggests only a modest undervaluation of the future fuel savings of more fuel-efficient cars.

There are also potential negative impacts on the external costs, because car sharing or on-ride demand services lower the barrier to use a car for people who previously did not have access to the car. Moreover, by reducing (or even eliminating) parking costs and searching time for parking it can make car use more attractive. Also, if the systems are devised as a substitute rather than a complement to public transport or other sustainable modes they may also lead to a modal shift in the wrong direction.

Important to note is that in all of these cases the decisions are still taken by the individual transport users, based on a consideration of the costs and benefits for themselves. The same is the case for the companies providing the services that are aiming at profit maximization. The latter point also means that even if the companies apply peak load pricing, this will also be based on private profit maximization.

Therefore, government intervention is required in order to guide the decisions in the correct direction from the social point of view.

Another potential effect of shared mobility is related to the public acceptability of road pricing, which is commonly quite low when plans for road pricing are discussed in public debate. The intermediary role of car sharing companies, TNCs, and MaaS providers may help to improve the public acceptability of road pricing (Hensher, 2018), when the charges are paid more indirectly via these companies, compared to the situation where they are levied directly on the private car users. As users are paying a service, shared mobility will make it easier to introduce road pricing, and to adapt tariffs by time and location. The service bought by users will include all costs of ownership per km, including road pricing and will contain choices towards more environmental friendly vehicles. Even more, it will become more obvious to the user that using a car during peak hours is more costly.

Autonomous Vehicles

Autonomous vehicles (also called self-driving vehicles) can provide benefits to the user, such as providing independent mobility for people that cannot or should not drive, typically 10%–30% of the population, which increases their options for various activities. Benefits to ex-drivers are mainly found in safety and comfort: driving time, which is on average 1 hour per day, becomes now time free to spend on other activities. It is expected that autonomous vehicles will increase transport demand, both due to the increase of

ex-non-drivers now driving, and of ex-drivers now driving more. Some studies estimate that transport demand might increase by up to 14% (Schoettle and Sivak, 2015; Trommer et al., 2016). In the long run, autonomous vehicles might encourage urban sprawl and even further increase transport demand (Milakis et al., 2017).

It has to be noted that we are still far from fully autonomous vehicles. Commonly, six technology levels are defined, where level 0 has no automation and level 6 is fully automated. Levels 1 (assisted driving such as cruise control) and 2 (monitored driving, e.g., automated parking and lane keeping) already exist. Up to level 3, a driver is still required as a fall back. Level 4 has a steering wheel for some driving modes. Level 5 has no steering wheel. Experts acknowledge that significant technical progress is needed before level 5 automation is reliable, tested and approved. Even if level 5 technologies penetrate new vehicle markets in the 2020s, it will be the 2040s or 2050s before most vehicles are capable of autonomous driving.

Shared autonomous vehicles have the potential to reduce private car ownership dramatically. Cars are currently used on average 1 hour per day, which is expected to improve to 5 hours when fully automated and shared. Larger amounts are unrealistic due to the nature of travel demand showing peaks in the morning and evening. However, part of this benefit will be lost due to empty driving while floating around for passengers (Henao and Marshall, 2018).

For the user, the cost will be shifting from a high fixed cost and a low variable cost towards an almost full variable cost. Compared to current shared vehicles automated vehicles will be more convenient because they can be available at the doorstep.

It is uncertain if the average cost per km will increase or decrease. Automated technology is more expensive than manual driving, but the sharing of the vehicle, and the more efficient use might lead to a reduction in costs. In any case, automated vehicles will be cheaper than taxis and public transport that require a paid driver. Estimates vary from USD 0.1 up to USD 1 per mile, depending on the transport mode.

More important, the value of time savings for drivers might drop drastically. According to Rodier (2018) the effects vary widely, but 75%–82% of current driver values of time may be reasonable.

Despite the possible increase in traffic, autonomous vehicles that are shared and thus used more often, have the benefit of a shorter life span enabling a faster penetration of new technologies, when available (see also the section on shared mobility). However, it is at the moment unclear if autonomous vehicles will lead to lower emissions. According to the World Energy Outlook of the International Energy Agency the consequences of automation on long-term energy demand and emissions could go in different directions, as various factors influence the final outcome (OECD/IEA, 2018).

Congestion levels can go up or down (Milakis et al., 2017), mostly depending on the technology (how platooning of autonomous vehicles will affect the road capacity) and the occupancy rates (efficient sharing of vehicles). A new type of external costs that will occur is related to the availability of vehicles during peak hours. An optimum has to be found in providing enough vehicles to cope with peak demand, and the higher costs of not using such vehicles during a large part of the day.

In general effects on traffic congestion, energy consumption, pollution emissions, roadway and parking facility costs are possibly beneficial, but uncertain and depending on the increase in transport volumes. As the value of time is expected to change downwards, and impacts on emissions and congestion are uncertain, it is hard to predict the levels of road pricing needed to balance out the external effects of transport.

Developments in Road Pricing Technologies

Road user charging is now widely implemented throughout the world. The charging schemes, however, vary considerably (Walker, 2018). At the moment, most charging is either a time-based vignette, a kilometer charge on the main motorways, or a city access charge. No large area-wide kilometer charges exist yet. The reason for this is partly technical: the only feasible way to charge all roads is to use satellite navigation based on-board units. With this, each car is equipped with a device that sends its satellite positions regularly to a central system that handles the mapping of the positions on a road network, and calculates the charge. Such systems exist for truck charging on motorways and main roads in Germany since 2005, with five European countries following later. Singapore is planning to use it for its motorways for passenger cars from 2020 onwards.

The most widely used technology at the moment is short range and microwave communication, with DSRC (dedicated short-range communication) as the most popular standard. With this, a vehicle is equipped with a tag, a small chip costing EUR 5–20, that can be identified with roadside equipment. Each time a vehicle passes such a physical barrier, it is charged. A large amount of motorways across the world is equipped with such a tolling system among which the US East coast states, France, Italy, Portugal, Norway, Dubai, South Africa, and the current system in Singapore. Though this system is easy to use and cheap for simple road networks, it is not expandable to the large network rural and urban roads due to the large amount of roadside equipment it would require.

Moreover, microwave communication is even becoming less popular for motorways and urban access roads, while ANPR (automatic number plate recognition) systems are slowly becoming the standard. With this, cameras at the roadside register every passing vehicle. No device is needed in the vehicle, making this the easiest technological system to roll out. As camera quality has improved a lot since the first tolling based on ANPR was introduced in London in 2003, most urban systems are now equipped with ANPR, and even some motorway sections now use it. However, it is a costly approach for large and complicated networks, as this would require a large amount of roadside poles and portals each of them equipped with a camera.

As stated before, road charging with satellite navigation based on-board units is the future and a large amount of countries are studying its use. The main challenge is the price of the device, now costing about EUR 60–100 each, and dropping. An interesting approach would be to use the drivers' own mobile phones and/or the in-car telematics as a device, making it basically for free.

However, this would require a certified app that can meet the demanding legal standards for taxation. Such developments are expected in the near future with a possible first application around 2025.

A Taxonomy of Appraisal Approaches

Cost–benefit analysis (CBA) is the most used assessment approach in public decisions concerning transport, but others exist. They differ substantially for disciplinary background, purpose, technicalities, but at the same time they share some concepts, typically the idea of weighting advantages and disadvantages of an intervention, or represent different facets of similar approaches. This translates into typical fields of applicability, but also in interesting potential cross-fertilizations. In this section, we will propose a taxonomy across assessment approaches, showing when they are really different and when they just represent different points of view.

Among the main dimensions that differentiate approaches, there are:

- The disciplinary background;
- Which markets are considered (analysis boundary);
- If the analysis is spatialized or not; and
- Who sets the weights/define what is benefit and cost.

It is important to notice that some of the following approaches have broader applications than (transport) project assessment. Consequently, looking at them as an “assessment technique” requires a redefinition and in some cases also a sort of stretching to adapt to the usual problems of transport economist deciding about one new transport infrastructure or a change in a mobility policy. For example, a CGE describes quantitatively an economy as a whole, by means of mathematical models, feedbacks, and elasticities. It is primarily a *model* and it is used to simulate what happens when something changes—a new road is build, for example, or a tax is risen. One can decide that when certain indicators are met, a project is worthwhile, making it also an assessment technique. But this is not directly an evaluation in the sense of CBA.

It is useful to start with a concise definition of the key features of the main approaches used.

(Social) Cost–Benefit Analysis (CBA)

CBA is a well-established method, founded in welfare economics, based on the quantification of all direct (e.g., time savings, investment costs, etc.) and indirect (e.g., pollution reduction benefits) effects of a transport investment, in terms of marginal utility variation, and their consequent monetization and discount. CBA assumes that the variation of utilities contributes to social surplus, whose maximization is the measure of worthwhileness. This means that the users’ benefits estimation is based on their evaluation/perception and not on an abstract measure defined by the analyst. The main use of CBA is to measure if the public intervention (including policies) improves the societal surplus and how efficient is the associated expenditure. Efficiency is clearly just one criterion among others, but this translates into a solid and univocal “meaning” of its results, often absent in other techniques. In

other words, the point of view of CBA is holistic, while other techniques tend to manage different points of view (MCA) or are not explicitly made to represent *one* point of view (any modeling exercise). Two main hypotheses lay behind CBA: the Kaldor–Hicks criterion (a measure is welfare-increasing, if benefits by winners exceeds the losses by losers) and the assumption that nontransport markets are not significantly affected (e.g., the price of energy does not change due to the project) or are perfect.

Cost Effectiveness Analysis (CEA)

CEA shares with CBA some operational features (quantification, monetization, discount, indicators), but is not assuming a superior criterion of choice, such as surplus maximization. In fact, it measures how effective is an expenditure in obtaining a result, whatever is the result and its measure. For example, CEA can either measure the cost-effectiveness of reducing CO₂ emissions, but also of increasing them (if someone aims to do that). In other words, CBA assumes intrinsically that some outcomes are benefits and other are costs, while CEA does not. Typically, they are set by the analyst or by politics (e.g., “road accidents must be halved”). Consequently, it is advisable to use it when it is clear and shared what is the desirability of the outcome measured.

Multiple-Criteria Decision-Making (MCDM) or Simply Multiple-Criteria Analysis (MCA)

MCA, as the name suggests, aims at dealing with multiple (and even conflicting) criteria, typically reflecting the objectives of different stakeholders. It is founded in operational research ([Charness and Cooper, 1961](#)) and consists in a ranking based on the optimization of criteria and relative weights. Monetization is not necessary and any quantitative or qualitative input can be in principle used. There is not one way to perform a MCA, but many methods and algorithms, each one with its characteristics, pros and cons ([De Brucker et al., 2011](#); [Macharis and Bernardini, 2015](#); [Pérez et al., 2015](#)). For example, basic MCA applications assume one decision maker, while current applications commonly take into account the multiplicity of stakeholders. Also different weighting methods and optimization algorithms exist. In MCA, what is a benefit is explicitly decided by the analyst (in simplest exercises, by the decision-maker or by involved stakeholders).

Input Output models (I/O) or Added Value Analysis

These tools, based on aggregate statistics of interdependencies between the branches of an economy or different regional economies, calculate the increase in added value of production, ignoring other effects such as externalities. Using this approach as an assessment technique means quantifying how 1 € of expenditure, which is 1 € of increase of direct production of some sectors, translates into (possibly) more than 1 € of outputs in other sectors. This apparently intuitive concept must be accompanied by some alerts. First of all, the use of this approach to evaluate the impact of one investment is basically pointless, because if substitution effects are ignored, *every* investment gives a positive added value. Secondly, the “cost” of this increase of production is not considered. If it comes from the external of the economy (foreign investment), the output could be entirely an added value, but if the expenditure comes from the inside, it is not “free” and probably requires an increase of taxation or a decrease of expenditure on other sectors. Thirdly, this technique assumes the invariance of productive structure and can therefore be used only for the very short term. Finally, it assumes a direct causality between inputs and outputs, which is not always the case.

Environmental Impact Assessment (EIA)

EIA is not an assessment technique in the sense of the previous ones. It describes the possible impacts of a project on environment, human activities, cultural heritage, and everything that is considered as scarce. EIA’s main output is the evidence of impact and their minimization, but this can assume the shape of an evaluation when these are considered as constraints or stakeholders’ goals. Clearly, this approach does not guarantee comparability among projects or the evaluation of trade-offs, which is the core, for example, of CBA.

(Spatial) Computable General Equilibrium Models (SCGE)

These models simulate what happens in an economy when something changes, through a series of equations expressing the production and market relations among parties ([Bröcker, 2014](#); [Bröcker et al., 2010](#)). Therefore, CGE do not intrinsically express a judgment. Using them as an assessment technique requires to decide what is the measure to be maximized and usually it is social surplus, like for CBA. The main differences with CBA are that they model all markets and can then be used to measure what happens outside of the transport market alone. They also focus on *households* and producers surplus, rather than on *users* and producers surplus. Aside to these interesting features, they require some alerts. Their formalization is not univocally defined and every CGE is different, according to author’s choices and available data, losing comparability of results. They must be calibrated with real world data to be usable, which is not simple at the scale required for transport modeling. They are very complex (and data demanding) because they must model the feedbacks between transport market and other markets, ignored by CBAs, and among regions.

Table 1 Main characteristics of assessment approaches

	<i>Foundation</i>	<i>Main point of view</i>	<i>Measure</i>	<i>Who sets weights</i>	<i>Assessment goal</i>
CBA	Microeconomics	Society as a whole	Welfare changes (via social surplus)	Users' choices	Economic efficiency of public expenditure
CEA	Microeconomics	Society as a whole	Specific performance indicators	Analyst/politician	Economic efficiency of public expenditure
MCA	Op. research	Stakeholders	Stakeholder's criteria	Stakeholders	Optimization of stakeholders' criteria
EIA	Env. sciences	Environment	(Environmental) impacts	Analyst	Minimization of environmental impacts
I/O	Macroeconomics	Country/region	Added value or GDP or employment	Cross-sector matrix	Maximization of added value, GDP, or employment
CGE	Microeconomics	Country/region	GDP, employment, welfare changes	Equilibrium	Simulate economy
SD	Op. research	Country/region	Surplus and specific indicators	Cross-sector matrix	Simulate spatial and transport assets

**Figure 1** Different boundaries of approaches.

System Dynamics Models (SD)

SD models (Rothengatter, 2017; Shepherd, 2014) may appear as CGE models, but with substantial differences. Similarly to CGE, they aim at modeling an entire economy to measure potentially any variable included (quantities, prices, welfare, etc.). Differently from most CGE, they are not economically micro-founded, they are not solved analytically but numerically and they do not imply an equilibrium, which in effect is not always true in complex phenomena like transport-economy relationship. Similarly to the other models, SD are not exactly assessment techniques based on a criterion, but being able to predict quantitatively the state of a system, they can be used to calculate indicators and/or to allow comparisons among alternatives.

The following tables schematize the main features of assessment approaches mentioned. Table 1 includes details about the disciplinary foundation of each approach, the main point of view entailed by the analysis, the measure at the basis of the assessment and the goal pursued by the approach. This last column is very important and clarifies the root of the judgment expressed apparently aseptically by an approach. For example, CBA pursues a general goal of economic efficiency of public expenditure measured through surplus changes, while MCA finds a “solution” best matching the different and contrasting points of view of the stakeholders involved. CGE and SD models do not assume a specific goal, but “simply” simulate what happens in the modeled systems. The judgment criterion is thus exogenous and in fact they are often used together with CBA.

Fig. 1 schematizes which are the relevant markets considered, which is a key feature of approaches and a powerful source of misunderstandings among experts. In fact, CBA assumes that most of effects can be measured in the transport market only. When this is not considered an acceptable proxy, wider economic effects are added. The same do LUTI models that include the land-use market into the transport model. The principle is that they include the *logsum* of transport choice models into a location choice model. This translates the fact that, in the long-run, location choices are no more independent variables, but are included in the feedback and consequently modeled and included among the impacts. CGE models instead assume that all interactions can be relevant and model an entire economy, however usually losing the spatial dimension that transport CBAs normally include.

Table 2 introduces further elements of comparison. All approaches are quantitative or allow treating also quantitative aspects. However, MCA and EIA can (and mostly) manage qualitative aspects. MCA and I/O are clearly dealing with a short-term perspective, the first because representing current stakeholders' view, the second because assuming constancy of productive structure. The other, with all the limits of long-term forecasting, aim to consider decades of effects. EIA and I/O are also unsuitable for ex-post analysis, while the remaining could—in principle—be used also to assess past choices, even if this is seldom done. The kind of output is very different. CBA, CEA, I/O, and MCA, despite different, create indicators and rankings whose function is to

Table 2 Main characteristics of assessment approaches

	<i>Quali/quantitative</i>	<i>Temporal scope</i>	<i>Ex-post</i>	<i>Output</i>	<i>Distribution matters?</i>	<i>Costs are</i>
CBA	Quantitative	Long term	Possible	Indicator	Not directly	Costs
CEA	Quantitative	Long term	Possible	Indicator	Not directly	Costs
MCA	Both	Short term	Possible	Score	Yes	Depends
EIA	Both	Long term	No	Prescriptions	Yes	Neutral
I/O	Quantitative	Short term	No	Indicator	Across industries	Benefits
CGE	Quantitative	Long term	Possible	Many	Yes	Costs
SD	Quantitative	Long term	Possible	Many	Yes	Costs

aggregate different aspects into one measure, that “automatically” inform the decision. EIA provides prescriptions based on the minimization of impacts, but no judgment or ranking of alternatives. Models are not aggregating results in one specific measure and can provide outputs on different aspects of the systems. Also for this reason they are not *exactly* assessment techniques, because not assuming one criterion.

Two other aspects are of some interest. Distribution of impacts, being one of the most relevant political criteria, is not the focus of all approaches and this—in a certain sense—explains why some approaches are more appreciated/understood by decision makers than others. CBA is intrinsically ignoring the distribution of impacts (rather summing all of them as if they were equivalent), but some recent applications split the NPV into NPV_i for the i involved parties (users, state, producers, polluted, etc.). The way costs are considered is also very interesting and explains a lot of the acceptability of assessment. Microeconomic approaches consider costs as *costs*: an expenditure enters in the assessment with a *minus* sign. Models in general and EIA are instead cost-neutral: they do not evaluate trade-offs. MCA and I/O models are more interesting. MCA assumes the criteria of the decision-makers. It is not uncommon that a local authority, for example, considers positive that an infrastructure (typically if paid by central administration) costs more, as it expects more benefits for the territory. I/O models calculate the multiplicative effect of an expenditure in the economy and then, in principle, any expenditure gives an added value. Therefore, an I/O model applied to one project alone, says that the more it is expensive, the better it is.

Cross-Approach Issues

Transparency, Complexity, and Reproducibility

There is a clear trade-off between transparency of results (i.e., how clear are the results and assumptions for a reader which is not the author of the analysis) and complexity. The apparently infinite computational capacity pushes analyses toward an extreme complexity, as if we were drawing a 1:1 map of the world. But an extreme complexity entails the impossibility to understand what is behind, in particular assumptions, limits, mathematical models, and feedback effects. This makes the assessment an apparently informative tool, but assumes a sort of *faith* in the reader. And when the readers are politicians and public opinion, faith could not be available and assessments can be refused or accepted uncritically according to one’s opinion, which is the exact opposite of the purpose of an assessment.

Therefore the key aspect—if we do not want to renounce to complexity—becomes credibility. A continuous, independent, comparative, and well-documented use of an approach makes it more credible. Ad-hoc evaluations, not documented and not reproducible, opaque, will be probably rejected by part of the readers. Here a list of elements that make an assessment exercise more accepted, whatever is its result:

1. Stable guidelines and methodology in general;
2. Continuous and comparative use, not project-specific;
3. Independency of the evaluator from the vested interests of the project assessed;
4. Separation of roles (modelist, evaluator, peer-reviewer, decision-maker);
5. Reproducibility, or at least transparency; and
6. Expost check.

Different approaches respond differently to the above factors. CBA is well-codified worldwide and if not reproducible, any CBA is at least understandable from everybody in the world. For MCA, instead, the recent approaches are more and more complex in weighting criteria and ranking solutions and many different algorithms exist, making the result more method-sensitive than any other approach. This is an advantage for acceptability, but also a problem when complexity reduces transparency and clarity of results. I/O models are quite simple and their complexity lays in the availability of reliable and sufficiently detailed data. This fact, together with the other elements mentioned, make them loved by politicians. CGE and SD, instead, make of complexity their distinctive sign. This is their main limit, and must be managed in the way listed above: stability, comparability, and credibility of the authors.

Equity, Distribution, and Conflicts

Conflicts are common when decisions must be taken under constrained resources (public money, but also environmental goods, time, and space). The main source of conflict lays in the distribution of benefits and costs associated to a project, especially in the long-run and out of the direct effects measured in the transport market (e.g., environmental or economic externalities). Moreover, these effects are also pretty hard to be measured. If everybody would gain forever and at no cost, conflicts would not exist or would be limited. However, often, a project gives large benefits to the few and spread small costs to the many (in terms of taxation, for example). Sometimes, there are even large costs to some groups, for example, for local externalities (e.g., a new highway crossing an environmentally sensitive valley). The way assessment approaches deal with conflicts, distribution of effects and ultimately equity is profoundly different.

MCA, which is conceived to manage different viewpoints, is more suitable to take into account and bring into the decision the distributive issues implicit in stakeholders' positions. On the other side, the result of MCA depends strictly on who is considered a "stakeholder." For example, in many applications, taxpayers are not sitting at the table (and hardly the elected politician can be considered as their representative) while the presence of locally impacted groups is dominating.

CBA is, in principle, inadequate to manage different points of view and conflicting objectives, simply because it assumes an aggregated measure of worthwhileness. CBA is not aiming at "being" the decision balancing the criteria at stake, but just to inform the stakeholders about the unique criterion of socioeconomic efficiency (including, under its perspective, many elements that are considered as criteria in other approaches, such as time savings, costs, and environment). However, CBA can be easily adapted to make explicit the distributive and equity impacts. In fact, instead of giving as output the aggregated indicators only, NPV can be split among involved groups. The level of such detail depends on the richness of available data, but the effect on main groups of users, polluted, state, operators, infrastructure managers, can be always computed. Interestingly, NPV can also be split spatially, when a transport model is available. It is also important to remember—and this has an impact also on transparency—that CBA assumes no weight (or, better, a weight of 1) for all impacts, once translated into the monetary units.

Another key point of CBA is the Kaldor–Hicks criterion, which assumes that parties can always compensate gains and losses or—more realistically—that from a collective point of view 1 € of loss for actor A is as important as 1 € gain for actor B. The effects of this assumption can be somewhat ignored when winners are users/citizens and losers is the State (in form of investment, taxes, etc.). But this is not always the case and different situations potentially conflict can rise. For example, some users win (the public transport users, e.g.) and others lose (the road users). Or producers gain, thanks to market power, more than what is gained by users (think for example what happens to fares when HS trains are introduced in monopoly conditions).

Distribution of impacts is also a concern of EIA, but it is treated just qualitatively and nothing is said about the equity. Other models—being models—are at best tools to evaluate distribution, but do not assume any judgment on it.

Political Acceptance

An institutional use evaluation requires to manage the complexity of multiple-objective and multi-actors political decisions, but also to limit, or at least to make more transparent, the arbitrariness of decision-makers. In this sense, is quite natural that setting a structured evaluation framework is hardly the first goal of a politician (Eliasson et al., 2015). At the same time, institutionalization means also to keep evaluation independent from politicians, not leaving them the freedom to use it or not.

However, not all approaches "limit" decisions in the same way and with the same rigidity. CBA is probably the most constraining approach, assuming one inclusive but very structured criterion. At the opposite of the range, MCA is designed exactly to maintain and manage the contradictions of different points of view. Other approaches are more perceived as a *tool* rather than a *rule*, like transport models or the other more complex models mentioned above (LUTI, CGE, etc.).

In this sense it is interesting that CBA is, despite the limited love of politicians, is worldwide the most adopted assessment approach. Reasons can be various.

1. assessment could be introduced (or often just promoted) in a legislative system from outside, for example, by international bodies (EU, WB, EIB, etc.);
2. politicians leave, while civil servants remain: in countries with a strong public administration tradition, assessment is promoted by it and just accepted by passing politicians;
3. into an administration, the payer is sometimes different from the buyer. This is the case when budget is spent by the Ministry of Transport but allocated by the Ministry of Finance, or when regions receive earmarked budget from central state. Therefore, rules are set—indirectly or not—by treasury rather than sectorial/local decision-makers;
4. a central administration could decide to introduce CBA as a strong tool to justify decisions based on efficiency rather distribution.

Actually, in understanding political acceptance of CBA as a decision tool, it is important to look at what is the role and the moment when it is used. A CBA whose results are legally binding politicians' decisions will be much less accepted (and promoted) with respect to a CBA whose role is to inform decisions, improve the performance, improve the transparency toward stakeholders. Put it simply, if $NPV < 0$ means *automatically* the rejection of a project, whatever is the opinion of the decision-maker, CBA will be less accepted (and typically never introduced). Instead, if a project can start even with a $NPV < 0$, admitting the prevalence of other justified criteria (regional distribution, equity, political strategy, etc.), the politician will be more prone to accept its result as an input for decision. The use of a MCA after a CBA is a way to rationalize this approach, which in some contexts is simply left to political debate.

CBA and Friends: When Interaction is Possible

For sure, a cross-fertilization among assessment approaches and techniques is possible and often needed to overcome reciprocal limits. At the same time, one must not ignore the deep differences mentioned above, assuming a naïve perspective of integration.

CBA and Transport Models

The first step for a CBA is to have reliable, but also detailed demand estimations, which in the case of transport must come from a transport model. In principle, CBA is suitable also for a back-of-the-envelope assessments, but these simplified exercises should be used carefully.

Transport models are needed not only to estimate the demand for an infrastructure, but also to obtain the generalized costs associated to the demand. In other words, in the typical surplus calculation, both quantities and costs derive from a multimodal equilibrium and must be used coherently to avoid paradoxical results (for example, a too small benefit with respect to large demand shifts would simply give absurd CBA results).

This apparently obvious integration brings a lot of practical complexity and even problems (Beria et al., 2018).

1. Models produce a lot of data, whose management is not effortless;
2. CBA is useful to point out local problems of a model, usually invisible to the modelist also during calibration (debugging);
3. Normally, surplus is calculated as a difference between generalized costs. But the CG should in principle be exactly the one of the model, including modal constants, calibration coefficients, and functional form. Any deviation will give a CBA incoherent with demand estimation (but not necessarily “wrong”).

Concerning this last point, it is worth noticing that sometimes this is required by guidelines. For example, when Values of Time used in the CBA must be the standard ones and not the ones derived from the calibrated model. A “perfect” integration between model and CBA is possible only using the *logsum* method, of which the *Rule of Half* is the most used proxy.

CBA and MCA

A first mating is between CBA and MCA. The relationship, however, is far from obvious (Annema et al., 2015; Beria et al., 2012), despite the interest of the literature and of decision-makers. There are three ways to integrate the two approaches, and they are very different.

1. MCA is used to quickly screen available options and exclude the worst ones, because dominated or because clearly unfeasible (e.g., one option much more complex than all other options but with similar effects). Survived options undergo a normal CBA.
2. A normal CBA is performed, but some relevant aspects remain unconsidered. For example, two roads have comparable costs and performances, but cross different landscapes or have very different authorization procedures because in two different regions. In this case, the CBA maintains its role and MCA compares the residual criteria only for worthwhile options.
3. CBA is one criterion of a MCA. This commonly used approach has many drawbacks. CBA often includes most of the relevant aspects and consequently MCA introduces unacceptable double counts. Secondly, CBA assumes a constraint (the budget) and one criterion (welfare maximization), and this is in contrast with a multi-agent approach, where criteria are different and constraints are not relevant. In common applications, MCA is de facto used to blend the results of a CBA, adding further criteria and weights. In this case, better to separate the two approaches, as the mix would lose most of credibility requirements listed above.

CBA and CGE or LUTI

A second combination is much more straight and synergic (Eliasson and Fosgerau, 2019; Rothengatter, 2017; Venables, 2007). CBA’s hypothesis of invariance of non-transport markets is often reasonable, but not always, as some investments can modify the market conditions upstream and downstream. In these cases, partial equilibrium models could be not sufficient and the obvious way to overcome this limit without leaving the CBA perspective is to “add” those effects that are additional to the direct ones (caring to avoid risky double counts). These effects are usually called “wider economic effects” and the way to calculate them is to use a CGE model including the transport system and the other relevant markets potentially influenced (labor, manufacturing, land use, etc.). The literature on this topic is still open, and well-recalled in other parts of this book, but extremely interesting in showing the complexity of such issue and—by contrast—the power of simplicity of CBA, when its hypotheses can be accepted.

CBA and EIA

EIA is not an evaluation technique in the sense of the other ones of this chapter, as it is not aimed to judge an investment or create a ranking among alternatives. It is rather used to clarify the impacts (environmental, but also societal, archeological, etc.) of a project, showing which alternatives impact less and which compensations or modifications can be imposed to the project to minimize negative impacts. In this sense, EIA shares the quantification of impacts with CBA (that monetize them), but also sets the constraints

to the project. Constraints translate into extra investment costs (for changes and compensations) and extra benefits (reduced negative impacts). It is worth noticing that a standard—like an environmental threshold that must not be passed—is, for CBA, an infinite cost.

Air Travel Demand The volume of passengers who travel by air, we consider the demand using commercial airlines in this article.

Income Elasticity of Demand The ratio of percentage change in demand to the percentage change in income.

Random Utility Theory A theory measures people's choice preference on goods or services by scoring and ranking the alternative using recognized utility.

Multinomial logit model One type of logit model which models the probability of choosing different alternatives.

Overview of Worldwide Air Travel Demand

In 1903, the Wright Brothers built the first powered aircraft. Since then, people have had a new mode of transport that is both high-speed and convenient. Currently, there are approximately 12 million passengers transported by nearly 8500 flights every day, and the demand is expected to continue growing over the next 20 years. Except for trips using general aviation, most air travel starts and ends with the approximately 290 commercial airlines registered in 120 countries.

Fig. 1 shows the real-time distribution of flights covering the earth at 17:00 on June 24, 2019, as mapped by VariFlight, and demonstrates a close relationship between economic level and flight distribution. Specifically, in the figure, the departure and arrival points of flights are concentrated in several regions: Europe, East Asia, the east and west coasts of the United States, and the Middle East (mainly in Saudi Arabia). Compared to other regions in the world, all the areas mentioned above are recognized to have better economic performances evaluated by indicators such as GDP, personal income, export–import volume, etc.

As tickets for air travel are more expensive than those for land-based or marine transportation, personal income is commonly regarded to have a great impact on the purchase of air tickets and further influence air travel demand (Brons et al., 2002). **Fig. 2** describes the distribution of worldwide personal income in 2017 (provided by World Bank). In the figure, the United States, West Europe, East Asia, and Saudi Arabia are the areas with high personal income of up to \$48,600 on average per year. We find that the areas with higher income in **Fig. 2** are those that attract more flights in **Fig. 1**; hence, it is reasonable to believe that personal income is positively correlated with air travel demand (Chin, 2002).

To further explore the relationship between income and air travel demand, we collected time series data from five countries: China, the United States, the Netherlands, the Philippines, and South Africa. All data are shown in **Fig. 3**.

We first compare the income and air travel demand levels in all the countries in **Fig. 3** in 2017. Personal income in the United States is 16 times higher than that in the Philippines (58,300 USD to 3660 USD), but the difference in air travel demand is more than 12 times (857,213,313 passengers to 66,703,257 passengers). Meanwhile, personal income in the United States is approximately 6.7 times higher than that in China; however, the air travel demand difference in these two countries is less significant (857,213,313 passengers to 551,234,500 passengers). Therefore, air travel demand does not appear to increase proportionately with the growth of personal income.

Figure 1 Real-time flight distribution. Source: <http://map.variflight.com/>

Subsequently, we examine the variation of personal income and air travel demand in China from 2013 to 2017. Personal income increased by 27% in these 5 years, while air travel demand increased by 52%. Meanwhile, air travel demand seems to be more stable in the Netherlands (high personal income), the Philippines, and South Africa (low personal income). Hence, it is reasonable to suspect that the relationship between air travel demand and personal income is S shaped. In particular, the demand will increase slowly when personal income stays at a low level and then grow quickly when personal income falls within the range of quick increase, and it will finally become stable as the income reaches a relatively high level.

How to Calculate Income Elasticity

In this section, we introduce two methods to calculate the quantitative effects of personal income on air travel demand. One is a classical method of measuring the income elasticity of demand, and the other is a logit-based method that can measure the elasticity of passengers' air travel choice probability to the change of personal income. The two methods are used to evaluate income elasticity from an aggregate perspective and a discrete perspective, respectively.

The Aggregate Method of Income Elasticity Calculation

The income elasticity of demand is a classic concept in the theory of microeconomics, and it is calculated as the ratio of the percentage change in demand to the percentage change in income (Marshall, 2009). The coefficient of income elasticity of demand E is calculated as Eq. (1), in which Q measures the volume of air travel demand, ΔQ is the change of Q , I is the personal income and ΔI donates the variation of I .

$E > 1$ indicates a high elasticity, in which case the increase in personal income will lead to a relatively large increment of demand; $E = 1$ indicates a unitary elasticity, in which case the demand will increase proportionately with the growth of personal income; $0 < E < 1$ indicates a low elasticity, in which case the increase percentage of demand will be less than the increase percentage of personal income; $E = 0$ indicates a zero elasticity, in which case the change of demand occurs regardless of income growth; $E < 0$ indicates a negative elasticity, in which case the demand will not increase but decrease with the growth of personal income. Normally, positive elasticity is associated with normal goods or services, negative elasticity always appears with inferior goods or services, and zero elasticity is associated with necessities.

$$E_m = \frac{\Delta Q/Q}{\Delta I/I} \quad (1)$$

The Discrete Method of Income Elasticity Calculation

In addition to the classical method that measures income elasticity using aggregated demand data, there exists another logit-based method using discrete data. The logit model is established based on the random utility theory. Eq. (2) is the utility function of

Figure 2 Distribution of personal income in the world. Source: <https://data.worldbank.org>

individual n from travel mode m , where V_{nm} is the observed portion while ϵ_{nm} stands for the random portion. In Eq.(3), V_{nm} is a function formulated by variable x_{nml} and the parameter β_{nml} , and personal income is a variable in the function of V_{nm} . ϵ_{nm} is an extreme value and is assumed to be independent of irrelevant distribution. Eq. (4) shows the specification of P_{nm} , which is the probability of individual n choosing mode m when ϵ_{nm} adopts a Gumbel distribution.

On the basis of Eq. (4), the income elasticity (E_{nm}) can be defined as the ratio between the percentage change in the propagability of choosing a specific mode (P_{nm}) and the percentage change in personal income I_n ($I_n x_{nml}$), which is demonstrated as Eq. (5). Due to the linear relationship between V_{nm} and I_n , Eq. (5) can be simplified as Eq. (6).

$$U_{nm} = V_{nm} + \epsilon_{nm} \quad (2)$$

$$V_{nm} = \sum_{l=1}^L \beta_{nml} x_{nml} \quad (3)$$

$$P_{nm} = \frac{e^{V_{nm}}}{\sum_m e^{V_{nm}}} \quad (4)$$

$$E_{mx_{nm}} = \frac{\partial P_{nm} x_{nm}}{\partial x_{nm} P_{nm}} = \frac{\partial V_{nm}}{\partial x_{nm}} P_{nm} (1 - P_{nm}) \frac{x_{nm}}{P_{nm}} = \frac{\partial V_{nm}}{\partial x_{nm}} x_{nm} (1 - P_{nm}) \quad (5)$$

$$E_{mx_{nm}} = \beta_x x_{nm} (1 - P_{nm}) \quad (6)$$

Case Study Using the Aggregate Method

Time Series Income Elasticity of Air Travel Demand

The aggregate method introduced in Section “The Aggregate Method of Income Elasticity Calculation” is applied here to measure the income elasticity of domestic air travel demand in China from 1999 to 2018, with the results being demonstrated in Table 1. The data on air travel demand and personal income are sourced from the China Statistical Yearbook, and the fourth column of the table demonstrates the income elasticity calculated with Eq. (1). In the calculation, the demand and income of the previous year are set as the baseline.

In examining the results, only one elasticity value is less than zero, indicating that the volume of domestic air travel demand in China decreased with the growth of personal income from 1998 to 1999. Referring to the Chinese air ticket pricing policy in the 1990s, it is easy to find that air tickets were fixed in 1999 as airlines suffered a great loss in prior years. Because of the increased air ticket prices, many passengers ceased traveling by air, leading to a demand decrease. Conversely, airlines were permitted to discount their tickets in 2000, hence the income elasticity calculated in this year is higher than 2. Therefore, it is reasonable to recognize air ticket price as an important factor that influences the income elasticity of air travel demand.

Table 1 Income elasticity of domestic air travel demand in China

Year	Air travel demand (1000 passengers)	Personal income (RMB)	Income elasticity of demand
1998	5205	5425	—
1999	5087	5854	−0.32
2000	6032	6280	2.31
2001	6832	6860	1.39
2002	7756	7703	1.09
2003	8078	8472	0.44
2004	11,046	9421	2.67
2005	12,602	10,493	1.21
2006	14,553	11,760	1.24
2007	16,884	13,786	0.94
2008	17,732	15,781	0.38
2009	21,578	17,175	2.20
2010	24,838	19,109	1.30
2011	27,199	21,810	0.70
2012	29,600	24,565	0.72
2013	32,742	26,955	1.08
2014	36,040	29,381	1.11
2015	39,411	31,790	1.13
2016	43,634	33,616	1.78
2017	49,611	36,396	1.58
2018	54,806.5	39,251	1.30

Source: China Statistical Yearbook

In addition, the average value of the calculated elasticity is 1.06 in [Table 1](#), suggesting that air transportation is a luxury service for passengers given the current income level in China. In addition, although Beijing hosted the Olympic Games in 2008, the income elasticity of domestic air travel demand was only 0.38 in that year, much lower than the average value.

Using the same method, we calculate the income elasticity of international air travel, and the results are shown in the fourth column of [Table 2](#). The averaged income elasticity in [Table 2](#) is 1.32, which is higher than domestic air travel in [Table 1](#). This is likely because international air travel is always much more expensive than domestic air travel ([Gallet and Doucouliagos, 2014](#)).

Table 2 Income elasticity of the international air travel demand in China

Year	Air travel demand (1000 passengers)	Personal income (RMB)	Income elasticity of demand
1998	526	5425	—
1999	631	5854	2.27
2000	690	6280	1.26
2001	693	6860	0.05
2002	838	7703	1.58
2003	682	8472	−2.52
2004	1077	9422	3.64
2005	1225	10,493	1.18
2006	1415	11,760	1.25
2007	1692	13,786	1.11
2008	1519	15,781	−0.90
2009	1474	17,175	−0.38
2010	1931	19,109	2.34
2011	2118	21,810	0.71
2012	2336	24,565	0.83
2013	2655	26,955	1.35
2014	3155	29,381	1.92
2015	4207	31,790	3.30
2016	5162	33,616	3.41
2017	5545	36,396	0.90
2018	6367	39,251	1.78

Source: China Statistical Yearbook

Table 3 Spatial income elasticity of air travel demand

Year	Beijing	Shanghai	Chengdu	Bangkok	Sydney	Dubai
2000	—	—	—	—	—	—
2010	1.10	1.19	1.24	1.42	3.49	6.83
2018	0.93	1.02	1.09	1.72	2.73	3.17

In the table, the income elasticities are less than zero in 2003, 2008, and 2009. The situation in 2003 was due to the outbreak of severe acute respiratory syndrome (SARS), which is an infectious disease with a high lethal rate. The subprime crisis that occurred in the United States caused the negative elasticities in 2008 and 2009. Due to the break of transnational collaboration and declined income, many business or leisure trips were cancelled during those 2 years. In addition, although the income elasticity in 2001 was positive, it was much lower than the average value in [Table 2](#). The 911 terrorist attacks may have led passengers to cancel their air travel for safety reasons.

As shown in [Table 2](#), it is obvious that the income elasticity values in 2015 and 2016 are very high. The situation is probably due to the Belt and Road initiative proposed by the Chinese government, which promotes communication and cooperation between China and other countries. Therefore, compared to the income elasticity of domestic air travel, international air travel is easily affected by policy, public emergencies and paroxysmal calamities.

Spatial Income Elasticity of Air Travel Demand

[Table 3](#) demonstrates the income elasticity of air travel demand for various international cities. In the calculation, the volume of air travel demand and the personal income in 2000 are set as the baseline. In the table, most income elasticity values for Beijing, Shanghai, and Chengdu are larger than 1, indicating that people in the three cities in China prefer the air travel mode.

However, in Bangkok, Sydney, and Dubai, the income elasticities of air travel demand are all greater than 1. For Bangkok, the Suvarnabhumi Airport opened in 2006, and the Don Mueang Airport opened its second runway in 2013, which may greatly stimulate air travel demand. In Sydney and Dubai, the reason for the high elasticity value is the rapid development of the tourism industry.

Case Study Using Discrete Method

In this section, the discrete method proposed in Section “The Discrete Method of Income Elasticity Calculation” is applied to calculate the income elasticity of air travel demand, and elasticity is here defined as the percentage change in the choice probability of air travel mode to the percentage change in personal income. In the calculation, the travel mode choice is first modeled based on a multinomial logit model; then, the data describing passengers’ choice behavior are collected using revealed preference (RP) and stated preference (SP) surveys. Finally, income elasticity is calculated on the basis of model estimation. Readers can find the fundamental theory of a multinomial logit model in the book written by [Train \(2009\)](#).

Considering substitutes for air travel, four alternatives are incorporated in the model: air, high-speed rail, normal rail, and nontravel. In the model, the passenger choice probability of each alternative is calculated by [Eq. \(4\)](#), in which the utility is formulated as in [Eq. \(2\)](#). To estimate the utility function, the RP and SP survey is designed to collect the data.

Model Estimation

The model was estimated by using the survey data; in the estimation, the survey data must be effect-coded, and the last level is set as the base level ([Cohen and Aiken, 2014](#)). Meanwhile, the full information maximum estimation method was employed for the estimation. The results are shown in [Table 4](#), and the utility function of each alternative is formulated as [Eq. \(7\)](#) to [Eq. \(10\)](#).

$$\begin{aligned}
 U(\text{Air}) = & 0.037 \cdot \text{INC_1} + 0.039 \cdot \text{INC_2} + 0.165 \cdot \text{INC_3} + 0.007 \cdot \text{PUR_1} + 0.060 \cdot \text{PUR_2} + 0.007 \cdot \text{PUR_3} - 0.003 \\

***Significant at the 1% level

**Significant at the 5% level

*Significant at the 10% level

The positive signs of the income coefficients (INC_1, INC_2, and INC_3) prove that passengers with a higher income plan more travel and accept higher travel costs. INC_3 has the highest coefficient, which means that the utility is higher for passengers with an income higher than 100,000 RMB per year.

In addition, air travel mode choice is also influenced by other variables. For example, the negative signs of PRICE and TTIME indicate that utility will decline with increasing ticket price and travel time. The coefficient of ATIME is statistically significant, and its sign shows that an increase in access time leads to a decreasing utility. The table further shows that utility is higher if the flight departs on time and then decreases with increasing flight delays, and the amplitude of decrease is related to the length of the delay. Similarly, the utility will rise when an air ticket can be changed for free (CFEE_1) but will decline if the change fee is higher than 0 (CFEE_2, CFEE_3).

In the group of flight times, FTIME_1 leads to a negative effect on utility, which shows the phenomenon that passengers do not prefer flights departing before 7:00 in the morning. The sign of the coefficient for ACTP_1 proves that passengers prefer to choose large aircrafts. In addition, the class of membership (CMFF) will lead to a positive effect: the higher the class, the more utility will be added.

Income Elasticity of Air Travel Demand

Based on the estimated utility function, the income elasticity can be calculated by Eq. (6). In the calculation, we assume that the values of other variables are fixed, and the values are demonstrated in Table 5.

Table 5 Assumed value of the variables describing the different travel modes

Modes	PRICE (yuan)	TTIME (hour)	ATIME (hour)	DTIME (hour)	FTIME	CFEE (yuan)	CMFF	CATP
Air	600	1.5	1.5	1	10:00	300	Regular	Boeing
High-speed train	400	4	1.5	0	9:00	50	—	—
Normal train	200	10	1.5	0	21:00	0	—	—

Table 6 Income elasticity of travel demand (income = 30,000 RMB per year)

	<i>Air</i>	<i>High-speed train</i>	<i>Normal train</i>
Elasticity	0.032	0.033	0.035

Table 7 Income elasticity of travel demand (income = 110,000 RMB per year)

	<i>Air</i>	<i>High-speed train</i>	<i>Normal train</i>
Elasticity	0.145	0.149	0.156

To calculate the income elasticity, we first assume that the income of passengers who travel for business is at least 30,000 RMB per year to calculate the income elasticity of air travel demand, which is shown in column 2 of **Table 6**. Then, assuming that the income of passengers who travel for business is at least 110,000 RMB per year, the income elasticity of air travel demand is calculated. The results are shown in column 2 of **Table 7**. In addition, we also obtained the income elasticity of travel demand for high-speed trains and normal trains.

As per the results in the above two tables, the income elasticity of travel demand will increase with income growth, indicating that people are willing to spend more money on travel when earning a higher salary (Jang et al., 2004). In addition, comparing the income elasticity for different travel modes, it can be found that the value of air travel is the lowest because air travel requires more expensive tickets, and passengers may switch to other modes when the air ticket prices increase (Yang and Zhang, 2012).

Conclusion

This article introduces the relationship between personal income and air travel demand and then proposes two methods of calculating the income elasticity of air travel demand from both the aggregate and the discrete perspectives. The aggregate method calculated the elasticity using the classical function provided by microeconomic theory, and the discrete method measured the elasticity based on the logit model constructed by the random utility theory. The results show the positive relationship between personal income and air travel demand and indicate that the economic background, government policy, public emergency, and paroxysmal calamity may all have significant influences on the income elasticity of air travel demand. Moreover, because of the expensive air tickets, the income elasticity of air travel demand is lower than those of other travel modes.

Nomenclature

GC: Generalized costs

GT: Generalized time

VoT: Value-of-time

Introduction and Understanding

In transport economics and transport modeling the term “generalized cost” (GC) typically refers to a sum of monetary and non-monetary costs of a journey weighted to a common base. Depending on the definition of the different weights, it can be expressed in either monetary units, time units, or any other unit defined by the modeler. In this sense, the concept of GCs provides a mean of summing all the significant and quantifiable elements of disutility arising from a transport journey or any other transport activity involving a measure of cost. It arose because it was found convenient, rather than as part of any theory. It is usually attributed to McIntosh and Quarmby (1970).

In the simplest form, it may be expressed as:

$$GC = c + f(q) \quad (1)$$

where GC refers to the generalized cost, c to one or more variables expressed in monetary units, q to a non-monetary variable, and f to a function that maps q into monetary units.

In practice, in transport economics and when applied in transport models, a more specific form is applied as shown in Eq. (2).

$$GC_{i,j,m} = c_{i,j,m} + w_m t_{i,j,m} \quad (2)$$

In this function, i and j represent origins and destinations while m represents a particular type of transport, which could be route or choice of mode. A common generalization is when $w_m t_{i,j,m}$ is expressed as a generalized journey time $GT_{i,j,m}$. That is:

$$GC_{i,j,m} = c_{i,j,m} + VoT \times GT_{i,j,m} \quad (3)$$

where $GT_{i,j,m} = w_{m,k=1} t_{i,j,m,k=1} + \dots + w_{m,k=K} t_{i,j,m,k=K}$

Here, $w_{m,1} \dots w_{m,k}$ represents different weights for different time components. To illustrate different $GT_{i,j,m}$ expressions, the following three common examples are provided.

1. For congested networks, congestion travel time is more annoying than “freeflow travel time.” A typical formulation often applied in road route choice models is given by:

$$GT_{i,j,m} = w_f t_{\text{freeflow}} + w_c t_{\text{congestion}} + w_t t_{\text{turntime}} \quad (4)$$

Here, t_{freeflow} represents freeflow time, $t_{\text{congestion}}$ congestion time, and t_{turntime} the time incurred when turning in intersections. All of the parameters w_f , w_c , and w_t measure different degrees of annoyance in the specific choice situation. As stated, it is generally found that $w_c > w_f$ reflecting that congestion is considered more annoying than freeflow time.

2. For public transport, walking time, waiting time, and interchange time are often considered more “painful” than onboard time. A commonly used form in public assignment models is:

$$GT_{i,j,m} = w_a t_{\text{walk}} + w_o t_{\text{onboard}} + w_s N_{\text{change}} + w_w t_{\text{wait}} \quad (5)$$

Here, t_{walk} represents walk time from the origin to the station, t_{onboard} the onboard time (often referred to as in-vehicle-time), N_{change} the number of changes, and t_{wait} the time incurred while waiting at stations in between trips.

3. For freight transport, where goods are transported in long and often complicated transport chains, it can be relevant to distinguish between transport time and lateness.

$$GT_{i,j,m} = w_t t_{\text{transport}} + w_l t_{\text{lateness}} \quad (6)$$

Here, $t_{\text{transport}}$ is the journey transport time and t_{lateness} expected lateness, possibly measured as some percentile of arrival time.

Note here that sometimes variables do not measure time but something else. N_{change} is one example of a variable not measured in time units, yet it forms part of the generalized time (GT). It is just that we have grouped all non-cost elements together and valued them in time units. Transport planners are often accused of being fixated on time savings, but in this case we are merely using a particular type of time as a base to allow us to treat everything on a fair basis, with each item having its own valuation relative to a common base. Other examples of variables that cannot be expressed as either time or money include, but are not limited to, the difficulty of boarding and alighting, the variability of journey time, and the ability to work while traveling.

Even more general expressions of GCs are common in the appraisal literature when studying social cost–benefits across a range of variables that express different external effects. Typically, this is based on a combined social surplus function that includes, apart from transport cost and transport time components, variables related to environmental costs and safety costs. Where it is not possible to establish a linear weighting function for an effect, a lump-sum valuation will need to be used for each “level” of that effect. For example, in considering the building of a new road, is the value of the loss of two trees exactly twice that of the loss of one tree? And, if two trees are to be lost, is that valued equally in a place where there are only two trees to begin with as in a place where there are 100? By weighting the different components with external cost estimates (typically provided by authorities) it is possible to calculate a social surplus function for a given policy. This measure of “consumer surplus” can then be benchmarked with respect to a neutral baseline and evaluated according to the cost it may incur.

For appraisal, the unit of measurement is always monetary units. Depending on the study, there may be many different types of external costs that vary with choice of mode and possibly also where and when the transport takes place. Air pollution and traffic noise as an example is less of a problem in rural areas and during nighttime compared to urban areas during daytime. Safety, on the other hand, will often be measured at the link level in order to account for differences in risk for different types of roads. At the general level this could be expressed as a GC that embraces all of these different components. At the level of $\{i, j, m\}$ it may be stated as a linear weighted function $\widetilde{GC}_{i,j,m}$ as presented in Eq. (7).

$$\widetilde{GC}_{i,j,m} = GC_{i,j,m} + a_s X_{i,j,m}^{\text{safety}} + a_{co} X_{i,j,m}^{\text{CO}_2} + a_n X_{i,j,m}^{\text{Noise}} + a_e X_{i,j,m}^{\text{Emissions}} \quad (7)$$

In this equation, the expression of generalized transport cost from before enters the model in monetary units as $GC_{i,j,m}$, while effects related to safety, CO_2 , noise, and emissions are all represented by separate linear models.

On the Justification of Generalized Cost

For appraisal studies it is common to assume fixed marginal external costs such that these are not influenced by the specific study or the specific model. Why? Because it implicitly imposes political standards for how infrastructure should be measured and benchmarked. If different weights across different areas and individuals were allowed, it would imply that two areas with the same challenges regarding congestion and traffic would be measured differently. As an example, if the value-of-time were allowed to vary by income, infrastructure investments would tend to favor rich neighborhoods all other things equal.

In the remainder of this paper, we will focus on the justification of GC from the perspective of a transport model. In this perspective, GC should be seen, mainly as a simplification of the underlying econometric model specification, which, one way or the other, will have consequences for the way we capture preferences and behavior. Insight can be offered by considering a simple discrete choice model with utility functions $V_{n,m}$ for agent n and mode m .

$$V_{n,m} = k_m + \alpha c_{n,m} + \beta t_{n,m} \quad (8)$$

This model can be estimated from micro-data or meso-data (if n represents a meso-data classification) and such estimation will typically render maximum likelihood estimates of alternative specific constants k_m and cost and time parameters α and β . The trade-off between time and money (the value-of-time) can be formulated as changes in time relative to changes in money:

$$VoT = \frac{\partial V / \partial t}{\partial V / \partial c} = \frac{\text{utility/time unit}}{\text{utility/monetary unit}} = \frac{\text{monetary unit}}{\text{time unit}} \quad (9)$$

In the case of a simple linear utility as presented in Eq. (8) the value-of-time function simply becomes ratio $\frac{\beta}{\alpha}$.

It can happen that $c_{n,m}$ and $t_{n,m}$ are correlated up to the point where it is difficult to estimate the parameters, and thereby their ratio with a sufficient precision. In econometrics this is referred to as the “parameter identification problem,” which is a serious and not easily solved problem. It is best to avoid it by either (1) careful model specification, (2) careful selection of estimation sample, or (3) by combining revealed and stated preference surveys where, in the latter, the levels of correlation can be better controlled when design the survey.

If the problem cannot be avoided, one can attempt to reduce the model to a form that can be properly identified. Removing one or more of the variables may obviously accomplish this goal, but introducing another challenge in that any policy analysis linked to the removed variables cannot be carried out. It is obviously a problem for most transport models if it cannot address the effect of either cost- or time-related variables as it may undermine the investigation of new infrastructure. A better approach is to fix one of the parameters and subsequently estimate a common scale parameter of either GCs or GT.

Generalized Cost—What Can be the Problem?

To understand what may be the problem of using a GC, consider a simple generalized additive cost function $GC_{n,m}$ (expressed in monetary units) that enters a utility function $V_{n,m}$. That is,

$$V_{n,m} = k_m + \alpha(c_{n,m} + \omega t_{n,m}) = k_m + \alpha GC_{n,m} \quad (10)$$

If the utility function is used in a corresponding discrete choice model, by assuming that individuals maximize utility over the choices m and by further assuming an error distribution that resembles IID Gumbel distributed errors, a choice probability model of the multinomial logit type emerges. That is,

$$P_{n,m} = \frac{\exp(V_{n,m})}{\sum_m \exp(V_{n,m})}, \forall n, m \quad (11)$$

Hereby, it is possible to consider how choice elasticities with respect to the GC depend on the value-of-time. Let $E_{GC_{n,m}}$ define the elasticity of GC, $E_{t_{n,m}}$ the travel time elasticity, and $E_{c_{n,m}}$ the cost elasticity. It is then easy to show, based on the definition of elasticities for the logit model, the two following identities: $E_{GC} = E_{t_{n,m}} + E_{c_{n,m}}$ and $\frac{\omega t_{n,m}}{c_{n,m}} = \frac{E_{t_{n,m}}}{E_{c_{n,m}}}$, where ω is the value-of-time. By combining these it is straightforward to see that:

$$E_{c_{n,m}} = \frac{E_{GC_{n,m}}}{1 + \omega \frac{t_{n,m}}{c_{n,m}}} \quad (12)$$

$$E_{t_{n,m}} = \frac{E_{GC_{n,m}}}{1 + \frac{c_{n,m}}{\omega t_{n,m}}} \quad (13)$$

This exposes some of the weaknesses of using a generalized travel cost approach, namely that (1) the elasticity of GC is a linear combination of the elasticity of cost $E_{c_{n,m}}$ and the elasticity of time $E_{t_{n,m}}$, and (2) the balance between the two is strictly controlled by the value-of-time. If the value-of-time is low, time will be considered less important compared to monetary costs, whereas the opposite is true if the value-of-time is high.

If a generic value-of-time is used for all modes, it may mean that for certain expensive modes, the balance between cost and time will become skewed and not reflect the true balance. This is acknowledged to be a problem when analyzing aviation and also high-speed rail.

So, in short, the main problem of using GCs is that the imposed weights often refer to other contexts and other time periods and thereby introduce a biased assessment of the different variables (Wardman and Toner, 2018). The implication may be that the balance between model sensitivity with respect to cost and time can be biased. This can lead to situations where a given assessment of travel time benefits is overestimated on the expense of the assessment of monetary cost that is then underestimated. References also include Kono et al. (2017) who noted that GC when applied as a mean to estimate trip demand may incur bias caused by the endogenous nature of the value-of-time. While this is certainly possible it does not provide much guidance on how then to forecast trip demand.

Generalized Cost or Generalized Time?

The term “generalized transport cost” suggests that the common generalization is expressed in monetary units. While this is certainly true when doing cost–benefit appraisal analysis, it is less common when applied in transport models. Consider the two expressions of indirect utility as either GT or GC:

$$V_{n,m}^{GT} = k_m + \beta(c_{n,m}/\omega + t_{n,m}) = k_m + \beta GT_{n,m} \quad (14)$$

$$V_{n,m}^{GC} = k_m + \alpha(c_{n,m} + \omega t_{n,m}) = k_m + \alpha GC_{n,m} \quad (15)$$

The question at this point is if it makes a difference whether we choose a formulation based on *GT* or *GC*? The answer is “it depends.” If solely judged through the glasses of an econometrician who seeks an identifiable model, there is no difference as $\frac{c_{n,m}}{\omega} + t_{n,m} \approx c_{n,m} + \omega t_{n,m}$. In other words, when estimating the model there is no difference and it is easy to assure that the sensitivity with respect to cost and time will be unaffected by the choice of model when evaluated on the estimation data. However, when considered from the perspective of applying the models it may have an effect. This is relevant when applying the model for forecasting purposes.

When applying transport models for forecasting, it is common to estimate a given parameter set and then subsequently apply this set of parameter for scenarios but with changes in variables that reflect the scenario. It is also common to assume that the value-of-time can change over time and that this change can be reasonably approximated by linking it to income growth. As productivity in society increases so should the value-of-time. In practice, this is typically expressed as an “income to value-of-time” elasticity. However, recent evidence (Rich and Vandet, 2019) suggests that, although there is strong empirical evidence for a positive income to value-of-time elasticity, changes in the value-of-time over time is affected by a variety of factors which, in addition to income growth, include increasing travel length and increasing congestion.

Consider the case of $V_{n,m}^{GT}$ from Eq. (14), where all we know about the future is a value-of-time ω that reflects that people are becoming wealthier relative to a general price index. As people become wealthier, costs tend to become less important to us. So in Eq. (14) we can think of ω as a “cost-deflation” factor, which when increased will put less emphasis on costs and in general cause the *GT* expression to decrease. As $\omega > 0$ and $\beta < 0$ this will lead to an increasing demand for longer trips as we maintain β throughout the forecast and keep all other things equal.

When used in the *GC* context of $V_{n,m}^{GC}$ in Eq. (15), the value-of-time ω represents what could be referred to as comfort affects, or rather the effect of discomfort. If ω increases while keeping α constant we can interpret this as increasing discomfort for longer trips, which in turn then would lead to increasing *GC* and broadly speaking a decreasing demand. Hence, in this forecast situation where ω is the only thing we know, the effect of using either of the two expressions is inversely proportional when measured through demand. In other words, whereas the model based on *GT* will tend to increase the distance of trips when the value-of-time is increasing, the opposite will be true for a model based on *GC*. The issue was first debated in Gunn (1983) who also acknowledged the difficulty of dealing with the issue.

As discussed earlier it is generally difficult to project the value-of-time in the future as it may depend on a variety of different factors from the development of new technology to the level of income. So even though it is clear that the value-of-time may change due to either changes in cost preferences or changes in time preferences or a mixture of the two, it is often not strictly possible to judge from which specific source a change occurs in the future. What the authors hereby want to convey to the readers is that modelers, when deciding on applying either *GC* or *GT*, in ways that are expressed earlier, implicitly impose an assumption on how the balance between cost and time sensitivity is projected.

At this stage it is relevant to give attention to the microeconomic framework proposed by Train and McFadden in their seminal paper from 1978 (Train and McFadden, 1978). In this paper, by forming a simple random utility framework with budget and time constraints, it is expressed how wages w are related to the utility of traveling and more specifically the attributes related to travel time and travel cost. It turns out that the utility specification in this simple case can be expressed as:

$$V_{n,m} = k_m \alpha (w^{-\theta} c_{n,m} + w^{1-\theta} t_{n,m}) \quad (16)$$

In the model θ can take on values between zero and one while α represents a common scale parameter.

The interesting observation here is that, if wages and the value-of-time can be assumed proportional, it follows that, depending on the value of θ , *GC* and *GT* represent two out of an infinite number of affine combinations of cost and time that form the indirect utility function. The *GT* arises as a special case when $\theta = 1$, whereas $\theta = 0$ resembles the case of travel cost. Why is this relevant? It is relevant because this framework, although presenting a nonlinear estimation challenge, provides a practical way of projecting the balance between cost and time in future scenarios that are different from the extreme cases presented earlier. The early findings of Train and McFadden suggested that $\theta = 0.7$ and therefore support the *GT* specification to a greater extent than the *GC* formulation. This suggests that time preferences are more stable over time which has been supported in other more recent studies (Fox et al., 2014; Rich and Vandet, 2019).

Conclusion and Summary

Generalized transport cost is a mean to combine different elements of travel (dis)utility. It is used in a number of situations in passenger and freight transport modeling, such as in route-choice models, public transport assignment models, and transport demand models in general (where time and cost components are accumulated over many different attributes). *GC* is also widely applied in appraisal studies of infrastructure and in other scenarios in that it forms the basis for a common monetary evaluation of a given policy.

The concept of *GC* may be expressed in any unit of measurement and is not restricted to monetary units. In transport models it is common to express the *GC* in either monetary units or in time units. In the paper, it is underlined that when models are applied to forecasting, choosing one form for the other may have consequences for the results. This can happen because, as the value-of-time increases, it will either deflate cost or increase travel time annoyance depending on the formulation. It is also illustrated, by a reference to Train and McFadden, how *GC* and *GT* may be combined and how the balance between them could be projected.

Introduction

Given the negative impact global energy systems have had on our planet over the course of the past century, a significant turnaround is now required if the still steeply increasing energy demand of the coming decades should not result in pushing our global environment further beyond its sustainable limits. As part of this required turnaround there has been a particular focus on the reduction of greenhouse gas emissions. Globally, these emissions are still increasing, even though this trend needs to be urgently reverted in order to minimize the social, environmental, and economic impacts of anthropogenic climate change. While the industrial sector—especially in developed countries—is already contributing to this target by reducing associated emissions, other sectors, such as the built environment, agriculture, and transport, are still increasing their emissions—which is in contradiction to the overall required emissions reduction target.

In regards specifically to the transport sector, this issue has only recently appeared on the agenda of politicians around the world (Creuzig et al., 2015), as it requires significant changes for the general population, as well as for established industries. Besides many other options, electric vehicles [in the following we focus on Plug-in Electric Vehicles (PEV), i.e., Battery Electric Vehicles and Plug-in Hybrid Electric Vehicles] stand out as an attractive option, as they do not require substantial and immediate changes in mobility patterns. PEVs are more energy efficient than fossil fuel vehicles and provide significant flexibility in fuel source in terms of electricity generation. Furthermore, if the ongoing transition in electricity generation towards renewable sources continues, over time it will lead to an “autonomous” and continuing decrease in the carbon-intensity of road transport through the adoption of PEVs.

Today, the integration of PEVs into the energy system appears to be an attractive solution for assisting in meeting global emission reduction targets (Jochem et al., 2015). PEVs—similar to conventional fossil fuel vehicles—are generally parked for long periods of time, providing the opportunity to provide energy services when they are not required to fulfil mobility demand. Additionally, consumers generally expect that PEVs should be capable of driving longer distances, despite the average daily distance of consumers being less than 50 km. This significant difference between stored and required energy, on average, presents a unique opportunity for this “excess” energy capacity to be used for purposes other than simply meeting mobility demand (Babrowski et al., 2014).

While PEVs present a number of opportunities for supporting electricity grids, conversely, if several vehicles are charged in parallel, at higher rates, and during higher demand periods on the electricity grid, these additional energy loads could place additional and significant stress on energy systems (Jochem et al., 2018).

Conversely, if the integration of PEVs into the energy system is in accordance with the principles mentioned below, multiple dividends may occur: PEVs can reduce greenhouse gas emissions from the transport sector while facilitating the integration of fluctuating renewable into the grid by providing load flexibilities across the wider system.

The main requirement of assuring a synergetic integration of PEV into energy systems is the charging strategy, which can be classified as follows:

1. **Uncontrolled charging:** As soon as the car is plugged-in the charging process starts at the maximum charging rate until the battery is fully recharged (i.e., State of Charge (SoC) equals 100%).
2. **Controlled charging:** The charging process does not necessarily start right after plugging-in, but after a signal is received (from the utility or user) for recharging the battery with flexible charging rates until a certain target SoC (e.g., 80%) within a defined time horizon (e.g., until scheduled car departure the next day).

3. **Bidirectional charging or vehicle-to-grid (V2G):** This charging process is similar to controlled charging, but provides another degree of freedom for load scheduling as the associated charging hardware provides the possibility to export electricity from the vehicle's battery back to the grid, when required. This mechanism significantly increases the flexibility of PEVs energy storage capabilities, but is associated with additional hardware costs and may also be associated with higher battery degradation.

Hazards of PEV Charging for the Energy System

One obvious hazard of PEVs to the energy system is the parallel charging of several PEVs at high charging rates. Even though other electrical appliances in private households create loads of several kilowatts, their stochastic application generally leads to a broad distribution over time, that is, the average load per household in distribution grids with dozens of households, levels out to approximately 1 kW, or in case of air conditioning, up to 3 kW. Exceptions to this could be during a heat wave in warmer climates, where electricity grids are already experiencing stress today.

Hence, if a large number of households plug in their vehicles at the same time in the evening, without any form of controlled charging, this could further exacerbate existing evening peak electricity demand. With many PEVs charging for one hour at 10 kW, the simultaneousness of this electricity demand is likely to be far higher than other appliances combined. This might lead to load peaks, which have not yet been seen in electricity grids. Even at a national level, peak loads may increase, which in turn could lead to additional required investments in the energy system, including grid expansion and additional generation. If this additional generation is not sufficiently provided by renewables, there is an additional risk that these higher loads would be met using carbon intensive energy generation, deteriorating the overall emissions reductions induced through the adoption of PEVs (Jochem et al., 2015). Alternatively, if the uptake of home battery systems continues, this additional localized energy storage may go some way to alleviating some of the pressure placed on the grid due to uncontrolled charging, noting that a home battery of 14 kWh (i.e., Tesla Powerwall 2), holds enough energy to delivery 30–40 km of charge while still having 50% energy reserved for other household appliances.

For example: in Germany some PEVs are already charged at a rate of 20 kW using three-phase power. Assuming a PEV market share of 100% (i.e., 40 million cars), this could lead to in an increase in the German electricity load by 800 GW, which would overshoot the current peak load by a factor of eight. The current development for fast charging stations along highways with charging rates in excess of 350 kW may even result in higher theoretical load peaks.

Empirically, we currently see that most PEVs are charged at lower rates at home or at workplaces—which makes the likelihood of this maximum load scenario unrealistic, however, increases in peak demand are nevertheless likely, highlighting the importance of implementing some form of charging control.

Synergies of EV Charging and the Electricity System

Increasing the Degree of Capacity Utilization of Grid Infrastructure

Today the workload of electricity grids in developed countries is embarrassing. The maximum load is rarely reached and during nights the operating grid is almost negligible. Grid profiles are generally “peaky” leading to the low utilization of many assets to cater for periods of demand that are high in load, but relatively short in time. As such, a flattening of grid load profiles could substantially multiply the energy throughput and efficiency of electricity grids. In residential areas, PEVs could play a significant role in filling the night load “valleys,” that is, they are generally parked overnight and connected to the grid, and they have high-energy demands (Fig. 1). Hence, a reliable, automatic control of PEV charging loads can offer a significant load shift potential—on average,

Figure 1 Exemplary V2G application for a distribution grid in Germany.

equivalent to the daily total electricity consumption of a single person household (around 8 kWh per day). Accordingly, given a high proportion of existing electricity fees in many nations is associated with the fixed costs of the grid, and the low utilization of some infrastructure, if deployed with control strategies, PEVs have the potential to increase energy demand without additional investments to the grid and, therefore, reduce electricity fees (per energy unit).

Integrating (Local) Provision of Electricity From Fluctuating Renewable Energy Generation

In many countries, renewable energy generation, particularly from solar and wind, is increasing considerably. This energy transition is going to continue over the coming decades and reverses the paradigm of “electricity supply following electricity demand” given electricity supply fluctuations will increase, leading to an increase in the share of curtailed electricity and, hence, inefficiency.

Flexible loads, such as controlled charged PEVs, can decrease the degree of curtailment. Many studies show that excess electricity from wind—especially in the night hours—can be suitably used for the controlled charging of PEVs. Furthermore, controlled charging increases the profitability of local decentralized electricity systems, such as photovoltaic solar systems, because PEVs can increase self-consumption rates (Kaschub et al., 2016; Seddig et al., 2019). As a consequence, PEVs can accelerate further investments in decentralized renewable electricity generation.

While further research is ongoing in regards to bidirectional charging, this technology has the potential to further accelerate the uptake of renewable energy given it can temporarily overcome local electricity shortages (e.g., dead calm) by exporting electricity directly from PEVs batteries. Note that a current battery capacity of an PEV is between 30 and 100 kWh, which is sufficient to cover the average two-person household electricity demand for between 3 and 12 days. This makes them also an attractive option where supply is unstable, for example, due to a weak electricity grid or for properties relying on self-supply. In many countries, if 100% of the car fleet was electric, the aggregate battery energy storage capacity would exceed the nation’s entire electricity demand for 24 hours, while still meeting the mobility needs of the fleet.

It should also be noted that used batteries from PEVs may serve as stationary energy storage through second-life applications, further supporting the economic integration and uptake of renewable energy. Overall, these co-benefits of PEVs can make electricity systems more reliable while decreasing their carbon intensity.

Decreasing Electricity Prices and System Costs While Increasing the Efficiency of Conventional Power Plants

One further incentive for encouraging load flexibility comes from the fluctuating prices of wholesale electricity markets. New business models are being developed which aggregate flexible loads for generating bids into different electricity markets, that is, lowering demand when electricity prices are high and increasing demand when they are low or even negative (Ensslen et al., 2018). In principle, the load flexibility of PEVs can be provided to all electricity markets from futures, spot, or ancillary service markets. V2G hardware further increases the potential of these services. The activities of these new energy market participants, the aggregators, and lead to decreasing average wholesale electricity prices and consequently to lower system costs. Furthermore, they maximize, on average, the utilization of the decreasing capacities of fossil fuel power plants. Again, overall, this leads to decreasing system costs.

User Acceptance of Load Flexibility

As (almost) no incentive for charging control is implemented yet, the user acceptance of these control mechanisms is unclear. An intelligent incentive for encouraging users to subscribe to those programs, and to behave correspondingly in their everyday life, is a tremendous challenge. A wrongly set incentive might even lead to undesired outcomes. Current research suggests that many PEV drivers hold positive attitudes towards such programs especially if the environmental benefits are highlighted. Many current users already combine a PEV with photovoltaic solar panels, home batteries and further smart home technologies, which underlines this interest. A frequent motivation expressed for adopting these new energy technologies is for consumers to increase their independence from the electricity system. In contrast, pilot projects have shown less enthusiasm for joining flexible electricity tariffs for other household activities and have pointed out that expectations of monetary rewards for flexibility provided usually exceed realistic market prices. In addition to this, only few very technically oriented users have a preference for manual control—most favor comfortable models which do not require expertise knowledge.

Taking these findings together, this highlights that business models need to be defined according to consumer needs: clear communication of how the system operates; the ability to override the system if needed; confidence and certainty in still obtaining the electricity required for the vehicle to fulfill the following day’s mobility services; and finally, a clear association between control strategies and lower electricity prices. However, it is also important to note that a strategy that mainly focuses on monetary motivation bears the risk to fail, as the perceived expense might be perceived as relatively high. More promising is the combination with other motives like enabling self-supply and autarchy, or a comfortable contribution to environmental goals, or additional services like a remote control of the vehicle charging in combination with anti-theft protection or a battery conservation program. It is important to note that monetary incentives do not only play a role as pure financial benefits but are also a means of communication to direct user behavior towards systemic goals.

Discussion and Conclusions

As the market share of PEVs continues to increase (Gnann et al., 2018), if they are charged without any control, electricity grids globally may be pushed toward their limits. Conversely, if the charging process can be controlled by an entity (e.g., the utility), this can lead to significant synergies between the electricity system and the decarbonization of road transport.

Today, distribution grid operators see PEVs often as a silent hazard as the market diffusion in a certain district can neither be forecasted nor observed—and after the first black-out it is already too late for grid extensions or control of the vehicles, because both solutions are time consuming. Hence, from a grid perspective the need for controlling PEV charging is key for the efficient and synergetic market integration of PEVs.

Technically, the control of PEV charging is relatively easy and has already been proven through implementation with many other technologies, such as night storage heating systems (Fig. 2). Today, the standards for communication between PEVs and the energy system are already in place: IEC 15118 assures an efficient communication between the car and the charging infrastructure (electric vehicle supply equipment, EVSE) and IEC 63110 outlines the requirements for processing the data exchange from the EVSE to the energy system. For controlled charging, communication with the EVSE seems unavoidable and therefore charging at domestic sockets will not be an appropriate long-term strategy. As such, PEV specific charging cords (cf. IEC 62196) together with intelligent EVSE are necessary. One exception might be a control signal (e.g., via GSM) to the on-board controller of the car. With all this in mind, it is important to note that to date, the controlled charging of PEVs has still only been applied in small field tests.

Besides charging control strategies, the load flexibility of PEVs also depends on consumer acceptance and individual circumstances: a charge on a long business trip may lead to minimal load flexibility while an average overnight charge at home provides much higher flexibility. User pattern analysis of conventional mobility data shows, however, that the idle time during the week at home exceeds in average 12 hours and is even significantly higher during the weekends. Hence, an average charge for 40 km (i.e., about 8 kWh) can be provided easily by a charging rate of less than 1 kW, which is far from challenging for the grid—even at a PEV market share of 100%.

Overall, the potential for mitigating greenhouse gases in road transport by PEVs is also dependent on the carbon-intensity of battery production and recycling processes. Today's production capacities are still dominated by countries with high fossil-fuel dependent electricity mixes, which can lead to undesirable environmental impacts. However, more recent production facilities already use local electricity from renewable energy resources, which makes PEVs (besides an increase in market shares of non-motorized traffic modes and car sharing) a significant opportunity for the sustainable, mobility transition.

While from a technical point of view the implementation of comprehensive charging programs mainly seems to be a question of time, user support for such a system change is also highly important. Finally, there is a promising chance that PEVs do not alone contribute to greenhouse gas reductions in the transport sector, but in the electricity sector, too. How these synergies are influenced by further developments in autonomous vehicles and car sharing is still unclear, but should also be considered in preparing for the uptake of this beneficial technology.

Biographies

Dr. Patrick Jochem is a postdoc at the Karlsruhe Institute of Technology (KIT) and Associate Editor of Transportation Research Part D: Transport and Environment. Since 2009 he is leading the interdisciplinary research group “Transport and Energy” at the Chair of Energy Economics and since 2012 the eMobility Lab at the Karlsruhe Service Research Institute (KSRI). He is author of more than 100 scientific peer-reviewed papers and has a strong funding record. In 2009, he received his PhD in transport economics, which was funded by the German Federal Environmental Foundation (DBU). In 2014, he was awarded by the Heidelberg Academy of Sciences and Humanities. He studied economics at the universities of Bayreuth, Mannheim and Heidelberg. His research interests are in the fields of electric mobility, energy system analysis, and ecological economics.

Dr. Jake Whitehead is the Founder and Secretariat of the Australia and New Zealand Clean Transport Coalition, a member of the International Electric Vehicle Policy Council, and holds two PhDs in Transport Science and Engineering. Dr Whitehead’s research primarily focuses on the costs, benefits, opportunities, and risks of clean transport technologies, as well as understanding the impacts of government policies on supporting and managing the uptake of these innovations. Dr Whitehead has also undertaken research on the synergies between clean transport and energy systems, in particular through the rollout of electric vehicle-to-grid systems, as well as the effectiveness of different transport technology pathways on reaching global emission reduction targets. Dr Whitehead has worked closely with governments and businesses internationally to advise on sustainable transport policies. These efforts have included coordinating the development of Australia’s most comprehensive electric vehicle strategy for Queensland.

Dr. Elisabeth Dütschke studied psychology, business administration and marketing at TU Darmstadt and RWTH Aachen. For her PhD thesis in organizational behavior at the university of Constance she received an award from Südwest Metall as an outstanding contribution to research. Further work experience includes consulting of private and public organizations and journalism as well as university lectures. Since June 2009 at the Fraunhofer ISI as senior scientist and project leader she has been involved in a large number of national and international research projects. Since March 2019 coordinator of the Unit “Actors and Social Acceptance in the Transition of the Energy System.” Her work focuses on the human perspective on a changing energy system. She is the main contact for societal issues around the energy transition for the institute.

Introduction

Horse-drawn carriages for hire were already present in Paris and London at the beginning of the 17th century: "It was in 1605 that hackney coaches came into use" (Gilbey, 1903, p. 26). By 1662, the number of hackney coaches in London had increased to 2490 and they were considered a "nuisance." In order to reduce their number, that year, a licensing system was introduced, with only 400 licenses granted (Gilbey, 1903, pp. 32–33). In 1637, "closed cars led by a coachman who responds to the calls of travellers" started operation in Paris, and about 20 years later, their number was also limited in Paris, through a cap of 600 licenses (Piot, 2015).

Horses were replaced with motorized transport but the hackney licenses have continued to this day, with similar systems in most cities throughout the world. At different points in time, but mostly over the 20th century, most cities also saw the emergence of private hire vehicles. Private hire vehicle companies and private hire vehicle drivers also need a license, usually granted by the local authority/municipality.

Taxis (or hackney cabs) and private hire vehicles are close substitutes. The main difference is that private hire vehicles need to be booked and cannot be hailed on the street or in a rank. The booking used to be done either in person in the company's premises or by telephone. Taxis can be booked in advance, hailed on the street, or picked up from designated taxi ranks. With the arrival of the Internet, businesses of all sorts, including taxi and private vehicle hire companies, started to build websites and in time, they also allowed bookings and sales online. As a result, by the beginning of the 2000s, it had become common for potential customers to use a search engine in order to book a taxi, a private hire vehicle, a flight, or hotel, among other goods and services. The arrival of smartphones with Internet connection signaled another milestone. The next step was, unsurprisingly, smartphone applications, that is, computer programs designed to run on mobile devices. Taxi and private hire companies then added GPS (which stands for global positioning systems) to the equation, to help dispatch, trace, and manage different taxis or private hire vehicles in a fleet, identifying drivers and passengers closest to each other, something that used to be done by radio or phone before GPS and the Internet.

This technology-enabled natural progression started well before Uber came into existence. Taxis and private hire vehicles have historically been subject to different regulations. This piece compares Uber and taxis, paying attention to various controversies and the different regulations they operate under. Uber started in 2009 and as of 2019, it claims to have at least 50% share of the private hire vehicle market in all the countries where it operates (Uber Technologies, Inc., 2019).

What is Uber?

Uber (<https://www.uber.com>) is a company that started in San Francisco, California, in 2009, and provides ride-hailing services. Over the years, it has added other services such as food delivery and bike-sharing. It is a very prominent name to the point that the emergence of the sharing economy, under which goods and services are not owned but accessed when needed, is often referred to as "uberization" of the economy.

Uber is an example of what Santos (2018) calls Model 3 of shared mobility. This Model 3 is referred to as ride-hailing, ride-sourcing, e-hailing, or transportation network companies. Under this model, companies act as brokers, matching drivers, who drive their own cars (or rented cars) and passengers. Passengers book rides through a smartphone application and are quoted a fare. When demand is high and there are not enough Uber cars to satisfy all requests, Uber fares go up. Uber calls this "surge pricing," and lets riders know the fare has gone up through the app at the time of booking.

One big competitor for Uber, worldwide, is Lyft (<https://www.lyft.com>). Other companies operating under Model 3 include Kapten (<https://www.kapten.com>), Bolt (<https://bolt.eu/>), and Xoox (<https://xoox.co.uk>), but there are many others, mostly operating in one or a few countries only.

The other models of shared mobility for cars and vans are Model 1 (peer-to-peer car rental, without a driver), Model 2 (modern car-clubs or car sharing, without drivers), and Model 4 (ride-sharing, ride-splitting, micro-transit, or new public transport on demand), all of which, like Model 3, rely on smartphone applications (Santos, 2018). Uber also offers UberPOOL, just like Lyft offers Lyft Line, both of which entail passengers sharing a ride. This type of service is cheaper because the ride and the costs are shared by passengers going in the same direction, who are picked up and dropped off at different locations on the same route. This falls under Model 4 in Santos (2018).

Controversies

Uber has been the subject of much controversy on a number of fronts. These have spanned from claims about unfair competition from the incumbent taxi industry, to employment status from the very Uber drivers, to claims that Uber and other ride-hailing companies increase traffic congestion, air pollution and CO₂ emissions, and take passengers away from public transport and active transport modes, like walking and cycling.

Incumbent Taxis

Uber and other ride-hailing companies are close substitutes of traditional taxis, as they provide transport services similar to those provided by taxi companies, and therefore compete with them. In Boston, Los Angeles, New York, San Francisco, and Seattle in the United States, the utilization rate of Uber drivers is higher than the utilization rate of taxi drivers, both when measured by time and by miles (Cramer and Krueger, 2016). Incumbent taxi drivers in the 50 largest metropolitan statistical areas in the United States have seen their relative earnings decrease by 10% after Uber's entry into the market (Berger et al., 2018). In the City of Toronto in Canada, Uber's entry is associated with a significant reduction in taxi trips (Young and Farber, 2019).

Regulations for taxis and for ride-hailing companies are different, as discussed further down. This has fuelled protests over the years from taxi drivers and taxi companies in a number of countries across all continents (BBC News, 2014, 2016).

The incumbent taxi industry argues that thousands of jobs are at risk because Uber and similar companies take their passengers away under unfair competition. We return to this point later on.

Drivers

For some time, but more so over 2018 and 2019, Uber drivers throughout the world have complained about low pay and poor working conditions (BBC, 2018a, 2019; Reuters, 2019; The Guardian, 2019). The key point is that Uber considers all Uber drivers to be independent contractors, or freelancers, rather than employees. Independent contractors are not entitled to a minimum wage or overtime, or health insurance, or scheduled breaks, or paid holidays.

As a result, in August 2013, Uber drivers filed a lawsuit in California claiming the company had to treat them as employees, not contractors, hoping to recover the tips they had never received and reimbursement for expenses such as fuel and vehicle maintenance (Lichten & Liss-Riordan, P.C., 2019). This was followed by the independent contractor status of Uber's drivers being challenged in courts and by government agencies in a number of other countries (Uber Technologies, Inc., 2019), including the United Kingdom (BBC, 2018b). The claim is that Uber drivers should be treated as employees or workers (Uber Technologies, Inc., 2019). Uber considers their drivers independent contractors because "they can choose whether, when, and where to provide services" on the Uber platform, and "are free to provide services on . . . competitors' platforms" (Uber Technologies, Inc., 2019). The matter is far from resolved and Uber "may not be successful in defending the independent contractor status of drivers in some or all jurisdictions" (Uber Technologies, Inc., 2019).

Sustainable Transport

On the one hand, ride-hailing increases traffic compared to private cars because there are extra miles on the way to pick-up (Schaller, 2018). In addition, collecting and dropping passengers also causes congestion (Erhardt et al., 2019). On the other hand, ride-hailing might be associated with lower car ownership and more frequent use of public transport and nonmotorized modes, and this could translate in a reduction in congestion (Feigon and Murphy, 2016, 2018; Smith, 2016).

Rayle et al. (2016) survey ride-hailing users in San Francisco, including those that use Uber. They find that ride-hailing could be increasing congestion. When asked what mode of transport ride-hailing users would have used had ride-hailing not been available, 8% would have not made the trip (which is evidence of induced demand for travel), 39% would have used a taxi (this is simply substitution), 33% would have used public transport (which carries more people and therefore congestion and emissions per passenger-mile are lower), and 6% would have driven their own car (which is substitution, but with the added miles on the way to pick-up). On similar lines, Clewlow and Mishra (2017) survey ride-hailing users in Boston, Chicago, Los Angeles, New York, San Francisco/Bay Area, Seattle, and Washington, DC and find that 49%–61% of ride-hailing trips would have not been made at all, or

would have been done by walking, cycling, or public transport, had ride-hailing not been available. If public transport patronage is decreasing because passengers are switching to ride-hailing, then the financial viability of public transport could be in danger. Furthermore, public transport is usually seen as the backbone of any sustainable city if congestion, air pollution and CO₂ emissions are to be minimized. [Clewlow and Mishra \(2017\)](#) also find that 91% of ride-hailing users who responded to their survey had not made any changes regarding whether to own a vehicle or not, in line with [Erhardt et al. \(2019\)](#), but in contrast with [Feigon and Murphy \(2016\)](#), who find that ride-hailing reduces the need to own a car.

Shared rides, however, could reduce congestion, air pollution, and CO₂ emissions when replacing solo trips made by car ([Furtado et al., 2017](#); [Schaller, 2018](#); [Viegas and Martinez, 2016, 2017](#)). The key here seems to be that for shared rides to yield these benefits, they need to replace solo trips, not trips by public transport. [Schwieterman and Michel \(2016\)](#) compare the different performance characteristics of UberPool and public transport services, both of which entail sharing a ride with fellow passengers, between downtown Chicago in the United States and the city's north- and northwest-side neighborhoods. Out of 50 trips that members of the research team took to and from the same location, starting at the same time, one by public transport and one by UberPOOL, 39 were faster with Uber. The average price was \$9.66 with Uber and \$2.29 with public transport. Although more expensive, UberPOOL could attract public transport passengers, especially during off-peak hours when there is no surge pricing in UberPOOL and there is no congestion on roads. This, again, would not be a good outcome for public transport because it would lose revenues. In addition, public transport in general can carry more passengers than any ride-sharing van or minibus, and thus minimize congestion, air pollution and CO₂ emissions, provided the bus/train/tram/etc in question is not (virtually) empty.

It should be highlighted that all these studies were done for US cities and may not be transferable to other regions of the world, where passengers may not switch from public transport, walking and cycling to ride-hailing (such as Uber) or to ride-sharing (such as UberPOOL).

One point that is widely recognized, however, is that ride-hailing can complement public transport. Although [Clewlow and Mishra \(2017\)](#) find that ride-hailing takes passengers away from public transport, they also find that ride-hailing is sometimes used to reach rail stations, and so, acts as a complementary mode for commuter rail services, with a 3% net increase in commuter rail use on average in Boston, Chicago, Los Angeles, New York, San Francisco/Bay Area, Seattle, and Washington, DC. These are the traditionally problematic first- and last-mile connections to and from public transport stations, where ride-hailing can provide a solution ([Erhardt et al., 2019](#), p. 1). Using data for Metropolitan Statistical Areas in the United States, [Hall et al. \(2018, p. 46\)](#) conclude that Uber complements public transport in cities where public transport patronage was low before Uber's entry, and substitutes for public transport in cities where public transport patronage was high before Uber's entry. They also find suggestive evidence that Uber is reducing commuting times for public transport users, because the first- and last-mile segments of a trip by public transport usually represent a small share of the distance traveled but a large share of the travel time, and by substituting for this segment, Uber can reduce the cost of public transport for the main segment of the trip ([Hall et al., 2018, p. 37](#)). This does, however, increase traffic congestion ([Hall et al., 2018, p. 44](#)).

On top of helping with the first- and last-mile problem, Uber and similar companies, can reach areas not well served by public transport, and operate at times when public transport does not, or at least, not frequently. Because of this, transport agencies in a number of European and North-American cities are exploring ways and even partnering with ride-hailing companies to provide first- and last-mile rides to and from public transport stations ([Crozet et al., 2019](#)).

Regulation

Competition is good. Consumers benefit from competition as they get the best services at the lowest prices, thanks to the rivalry between different suppliers. Competition pushes prices down and quality up.

The tension that has emerged between taxis and Uber is that competition may not be taking place on a level-playing field. Interestingly, while taxis complain that Uber is not subject to the same regulations, Uber complains that taxis are not subject to the same regulations. The reality is that regulations differ and the question is whether regulations should be the same for both so that they can compete on everything, or different, allowing ride-hailing companies and taxis to compete only on some features.

As highlighted in the introduction, one important difference between taxis and private hire vehicles, which include ride-hailing, such as Uber, is that taxis can be hailed on the street, on taxi ranks or booked in advance, while private hire vehicles can only be booked in advance.

Although quantity caps may reduce consumer welfare due to lower taxi availability and longer waiting times ([Competition & Markets Authority, 2017](#)), often, the number of licensed taxis is capped. This is the case in New York and Paris, for example. In contrast, the number of private hire vehicle licenses is typically not capped. New York, however, approved a cap on ride-hailing car licenses in August 2018. This was followed by the Mayor of London, Sadiq Kahn, making a similar proposal, arguing that the substantial increase in the number of private hire vehicles on London's roads in recent years had increased congestion and air pollution, and had left many drivers of such vehicles struggling to make enough money ([BBC News, 2018c](#); [The Guardian, 2018](#)). Three years before, the previous Mayor, Boris Johnson, had pushed for the same powers ([London Government, 2015](#)).

The fares that ride-hailing companies, such as Uber, charge are not capped or regulated either, whereas taxi fares tend to be heavily regulated. An argument for regulating taxi fares is that "passengers are in a relatively weak position to compare offers and negotiate prices in the hail and rank (taxi) trade" ([Competition & Markets Authority, 2017](#)), unlike in the private hire vehicle market. Taxis have a meter fitted within the vehicle, which calculates the fare for a journey, which also has a floor and a cap, and in some cities, an

extra fee during rush hour or at night time or when carrying luggage. The passenger typically knows the final price of her journey once she reaches her destination and the meter stops.

Ride-hailing companies such as Uber, on the other hand, are free to charge any fare, although the fare is shown to the customer in advance at the moment of booking the ride. Typically, fares are low when demand is low and high when demand is high. There is no meter fitted in Uber (or any other ride-hailing) vehicles. When ride-hailing companies charge very low fares, this can be expected to trickle down to the driver, who gets a low pay for her work. In December 2018, the New York Taxi and Limousine Commission passed regulations on new pay rates for drivers providing for-hire services in New York City and surrounding areas ([Uber Technologies, Inc., 2019](#)). This translated in Uber increasing the fares it charges in the affected areas. Although the regulator in this case did not impose a price floor directly, by imposing a minimum pay rate for drivers, it effectively did.

In addition to the above, in some cities such as London, taxi drivers need to pass knowledge tests demonstrating they know all the roads and back roads in the city, whereas private hire vehicle drivers need only pass a more basic test, where they are allowed to use GPS to find their way around. In the United States, Uber drivers do not need to pass any test at all; all they need is a driving license. The type of driving license required is different in the United States and in Europe. Most countries in Europe require Uber and all ride-hailing drivers to hold professional driving licenses. That is why UberPOP, which is the version of Uber with the ordinary driver, does not exist in Europe. Instead, the service offered is UberX, where the driver holds a professional driving license.

In London, black cabs, which incidentally are all wheelchair accessible, are exempt from paying the congestion charge, but private hire vehicles, including ride-hailing ones like Uber, are not, unless they are wheelchair accessible. Similarly, taxis are allowed to use bus lanes, but ride-hailing vehicles like Uber are not.

All taxi and private hire vehicle drivers, including ride-hailing drivers, are in most towns and cities throughout the world, subject to medical and criminal/background checks, need to hold insurance, and have their vehicles inspected periodically, among other matters.

Taxi and ride-hailing regulations have some similarities but they also differ. If regulations differ, taxis and Uber will only be able to compete where they can compete. Taxis in New York, for example, have extended their geographic coverage outside Manhattan, as Manhattan has been partly grabbed by Uber. This wider coverage has benefited customers ([Kim et al., 2018](#)). In London, incumbent London taxicabs accept credit card payments, which they resisted for years ([BBC News, 2017](#)). [Wallsten \(2015\)](#) also finds an association between Uber's increasing popularity and a decrease in consumer complaints about taxis in both New York and Chicago, which, he claims, may be possible to attribute to taxi drivers being more courteous to passengers as a result of the competition they face from Uber.

[Cramer and Krueger \(2016\)](#) find that in the United States, the capacity utilization rate is 30% and 50% higher for UberX drivers than taxi drivers, when measured by time and by miles, respectively, and they argue that two of the reasons for this are inefficient taxi regulations, and Uber's flexible supply model and surge pricing.

Whether regulations should be homogenized or not is a matter of debate. Homogenizing one regulation, may require homogenizing others. If fare regulation were scrapped for taxis, and these were able to fully compete on price, or if ride-hailing companies were subject to the same fare structure as taxis, then ride-hailing vehicles such as Uber would also probably be allowed to pick passengers up on streets and ranks, and neither type of vehicles would be capped or both types would receive the same number of licenses. This would make both offerings essentially identical, leaving the remaining differences to subtle details of service differentiation, such as for example, the type of knowledge test that drivers need to pass.

Discussion

After only 10 years of starting operations, Uber claims to have a market share within the private hire vehicle market of at least 50% in all the countries where it operates. The growth of the company is impressive, by any standards.

What is curious, however, is that Uber grew without offering a new, original, product. By 2009 most cities throughout the world had had private hire vehicle companies for decades. These companies matched drivers and passengers close by and accepted bookings via the Internet. Most drivers in these companies drove their own vehicles, just like Uber drivers do.

One controversial element is that originally Uber drivers did not hold professional driving licenses but normal driving licenses. This is still the case in the United States and some other countries. This may have helped charge very low fares and operate with great flexibility, to attract passengers from taxis, as well as from public transport, walking and cycling, and to induce trips that would have not taken place had Uber not been an option.

However, in many countries, Uber drivers are now required to hold professional driving licenses. Their fares are not regulated yet but New York has gone as far as setting minimum pay rates for drivers and limiting the number of private hire vehicle licenses, so the regulations under which ride-hailing companies are operating are starting to resemble those for taxis.

Capping numbers is a text-book example of a "command-and-control" policy. This may ultimately reduce the choice available to customers, but it may also contain the increase in traffic and congestion, air pollution and CO₂ emissions caused by ride-hailing companies, at least in those cities where this has been proved to be the case. In London, all ride-hailing companies, including Uber, used to be exempt from the congestion charge. This changed in April 2019. All private-hire vehicles, including Uber, pay the congestion charge now. As a result, Uber passengers are charged an extra pound for journeys going in, going out, or taking place inside the congestion charging zone, to help cover the £11.50 daily charge that drivers have to pay ([The Independent, 2019](#)). Despite ride-hailing companies paying the congestion charge in London, the Mayor is applying for powers to introduce a cap, as highlighted above.

Ride-hailing services could potentially focus on trips that increase social welfare. Three such examples are: (1) When ride-sharing replaces solo trips by car (as congestion, air pollution and CO₂ emissions per passenger-mile are lower); (2) When ride-hailing reaches areas not served by public transport, or is used when public transport is not in operation, such as for example, at nighttime; and (3) When ride-hailing facilitates first- and last mile connections to and from public transport stations. This could, however, increase congestion, air pollution and CO₂ emissions in the proximity of busy public transport stations.

Mobility as a Service

A word needs to be said about Mobility as a Service (MaaS), a concept that can be considered “the currently most widely discussed and hyped concept in the transport domain” (European Metropolitan Transport Authorities, 2019). The International Association of Public Transport (2019) defines MaaS as the “integration of, and access to, different transport services (such as public transport, ride-sharing, car-sharing, bike-sharing, scooter-sharing, taxi, car rental, ride-hailing and so on) in one single digital mobility offer, with active mobility and an efficient public transport system as its basis.” The idea is that MaaS provides mobility solutions that are consumed as a service. It offers integrated planning, booking, and payment for journeys, including multimodal journeys, through a digital platform, helping users satisfy all their travel needs without owning a car.

Uber can be part of MaaS and is so keen that it is a member of the MaaS Alliance and its Board of Directors (<https://maas-alliance.eu/maas-alliance-partners-uber-support-shared-mobility/>). The aim of the Alliance, as stated on their website, is to provide an alternative to the private car that is efficient and sustainable. Interestingly, there is no mention of public transport or active transport as being the main alternatives to the private car or the “basis” of MaaS, as defined by the International Association of Public Transport (2019).

Regardless of whether Uber complements or substitutes for public transport, Uber can increase congestion, air pollution, and CO₂ emissions simply by increasing the number of trips taken (Hall et al., 2018). However, Uber’s impact on road transport externalities will be larger if it substitutes for public transport (Hall et al., 2018). The evidence for the United States is mixed, with some work pointing towards Uber being a substitute and some work pointing towards Uber being a complement. Interestingly, when filing to go on the stock market, Uber itself publicly declared that they plan to target public transport passengers in the long run:

“We address a massive opportunity in powering movement from point A to point B... We view our market opportunity in terms of a total addressable market (‘TAM’), which we believe that we can address over the long-term . . .

Our Personal Mobility TAM consists of 11.9 trillion miles per year, representing an estimated \$5.7 trillion market opportunity in 175 countries. We include all passenger vehicle miles and *all public transportation miles in all countries** globally in our TAM, including those we have yet to enter . . . ”

(Uber Technologies, Inc., 2019, p. 10) *Emphasis added by the author.

Conclusions

Uber is a ride-hailing company that started in 2009 and 10 years later has at least 50% of the private vehicle hire market share in all the countries where it operates (Uber Technologies, Inc., 2019). It has been a subject of controversy, with discontent from the taxi industry, from its own drivers, and a debate on whether Uber and similar companies are to blame for increases in congestion, air pollution and CO₂ emissions in a number of cities in the United States.

The set of regulations under which Uber and taxis operate is different. This has caused tensions but it is unclear whether regulations should be homogenized. Under current arrangements, there are arguments for regulating taxi fares, as potential passengers hailing them on the street or at taxi ranks are not in a position to negotiate prices. Most cities also have price floors, protecting taxi drivers, and price caps, protecting passengers. These arguments do not apply to Uber or ride-hailing companies in general. However, if Uber and other ride-hailing companies were allowed to pick passengers up on the street like taxis are, then there would be an argument for homogenizing fare structures. Similarly, if ride-hailing cars were made wheelchair accessible like taxis are, there would be an argument for exempting them from the congestion charge in London.

If they remain close substitutes subject to different regulations, taxis and Uber will only be able to compete on what they can compete. Uber vehicles cannot be hailed on the street but they can attract passengers by charging very low fares. Taxis cannot compete on price, but they can be hailed on the street and they can ensure they provide a good quality service by drivers being polite and accepting card payments.

Ultimately any change in regulation should aim at helping Uber and other ride-hailing companies, as well as taxis, benefit consumers, as long as they do not substitute for public transport. Public transport and active transport, not ride-hailing or taxis, should be the backbone of any sustainable urban transport system.

Introduction

When a production technology is characterized by increasing returns to scale, the regulator in charge of the organization of the service prefers to keep the monopoly status of the firm in charge of the operation. The key issue is then to design the best regulatory contract that guarantees that the activity of the firm coincides with the objectives of the regulator. In particular, the question of the incentive power of the contract in terms of the reduction of the operating costs is a particularly important issue given that it is the society as a whole that will bear the costs associated with the provision of the service.

This chapter focuses more specifically on the urban transport industry, which is usually seen as a universal service in developed countries, and where operating costs are much higher than commercial revenues and therefore require that the regulator pays the operator a socially costly subsidy. Controlling operating costs is therefore an important issue for the regulator, which ideally aims at selecting the most efficient firm to provide the service. Our objective in this chapter is to present a literature review on the relationship between the productive efficiency (the cost) of a transport operator and the incentive power of the regulatory contract that defines the cost reimbursement rules of the transportation activity. The economic analysis discussed here is usually based on the estimation of a cost function or a cost frontier, which usually incorporates an inefficiency variable. We suggest that the literature usually agrees on the fact that contracts with higher incentives lead to larger cost reductions. However, we also shed light on the fact that to identify a causal effect of a type of contract on cost efficiency is a tricky task as efficiency and the choice of the type of contract are usually jointly determined, which causes problems of endogeneity.

We present in the second section a set of estimation techniques based on reduced forms that do most of the time assume that contracts are exogenous. Then, in the third section, we focus instead on more structural approaches that do explicitly represent in the structure of the estimated cost function the source of the potential endogeneity problem. These techniques are based on a tradition initiated by Leibenstein (1966) which considers that any cost expenditure should be affected by a global inefficiency index that depends on the firm's technical ability but also on the will of the managers and workers involved in the production process. On the one hand, a low-powered incentive environment due to a lack of productivity of working agents induces the inefficiency, whereas appropriate incentives can lead to significant operating cost reductions. On the other hand, since the emergence of the new theory of regulation, economists admit that, in industries where a producer is regulated by an authority, the principal-agent relationship is at the core of the question of assessing the performance of a firm. (Baron and Myerson 1982; Laffont and Tirole, 1986; Loeb and Magat, 1979). The incentive models provide a relevant framework for the analysis of operating cost in public transport activities. In addition, because such models are able to elicit the structural relationship between the observable variables and the inefficiency term, they directly provide a way to deal with the endogeneity of the inefficiency term, that is, with the stumbling block of the econometrics of frontiers. Hence technical inefficiency and effort are two unobservable parameters, which characterize the incentives faced by a firm to reduce costs and define the source of global inefficiency.

Reduced Forms

The efficiency of a firm is typically measured from a production or a cost function, as both are a dual representation of the same technology. Cost expressions have been more popular given that the public transport industry usually considers that output levels are set by transport authorities. The researcher may be interested in the direct relationship between the operator's cost and several explanatory variables or may attempt to estimate an efficiency index that is incorporated directly in the cost structure. We present in this section the different types of functional form used by the researchers and we shed light on how the contract effect is accounted for. We present a first set of cases where contracts are assumed to be exogenous. Then we discuss several papers that relax this hypothesis and attempt to explain in a simple way how the choice of contract can be identified.

Contract Choice is Exogenous

French data on urban transportation have been very popular in the economic analysis as there is quite a long tradition on collecting data on the activity of both transport operators and local regulator in each urban area of significant size. A local authority (i.e., a municipality, a group of municipalities, or a district, whose councils are elected for six-year terms) is in charge of regulating an operator, which has been selected to operate the network, that is, to provide the transport services. This framework has been recorded in a law on the organization of transport services within France enacted in 1982, which established the principle of the decentralization of these services to local authorities from the State and provided guidance and rules for their regulation. As a result, each local authority organizes its urban transportation system by setting the route structure, the level of capacity and quality of service, the fare level and structure, the conditions for subsidizing the service, the level of investment, and the nature of ownership. It may decide to operate the network directly or to require the services of a transport service provider. In this latter case, a formal contract sets the terms of reference that the operator must comply with as well as the payment and/or cost-reimbursement rules between the authority (the principal) and the operator (the agent). [Gagnepain \(1998\)](#) focuses on a panel data set covers 49 different urban transport networks over the period 1987–2001. Two types of regulatory contracts are implemented, namely, cost-plus and fixed-price schemes. Under fixed-price contracts, operators receive subsidies to finance the expected operating deficits; under cost-plus regulation, subsidies are paid to the firms to finance ex post deficits. Hence, fixed-price regimes are very high-powered incentive schemes, while cost-plus regimes do not provide any incentives for cost reduction. The identification strategy of the paper is built upon a reduced-form model, which provides insights into the effects of certain variables without requiring a complete modeling of the environment that characterizes the production activity. More in particular, a reduced Translog cost function is used to support the estimation of operating costs. A variable, which characterizes the type of regulatory scheme in operation, is introduced to study the effect of the latter on costs. The results indicate that firms regulated by fixed-price contracts have an average cost of 2.05% lower than firms regulated by cost-of-service schemes, hence suggesting that a transport company has an incentive to reduce costs depending on the type of contract that the local authority offers.

[Kerstens \(1996\)](#) uses the same type of data but works on a smaller sample (114 observations). This study also differs from the previous one as it is based on a two-step estimation procedure: First, the author estimates a production frontier for the transport operators using data envelopment analysis ([Farrell, 1957](#)). In a second step, the determinants indexes of the performance of French urban transit companies are investigated with a Tobit model. The empirical results show that higher efficiency measures are observed more often with fixed-price contracts. [Roy and Yvrande-Billon \(2007\)](#) and [Gautier and Yvrande-Billon \(2013\)](#) use the same type of data but focus instead on a stochastic cost frontier ([Aigner et al., 1977](#); [Meeusen and van Den Broeck, 1977](#)) where some of the deviations from the frontier are attributed to inefficiency, as suggested by [Battese and Coelli \(1995\)](#). Their results suggest that operators under cost-plus contracts exhibit a higher level of technical inefficiency than operators under fixed-price agreements.

[Vigren \(2016\)](#) investigates how common contract types and contract design factors in the Swedish public transport system affect cost efficiency. There are three different types of contract, which entail significant incentives, as in a fixed-price regime: On the one hand, a gross-cost contract without incentives implies that the operator receives a fixed payment based on the supply objectives set by the regulator; in this case, the operator bears only the production “risk”, that is, it is responsible for potential cost-overruns and it obtains a positive profit if the ex post cost is below the expected cost defined ex ante. On the other hand, the net-cost contract implies that the operator bears both industrial and commercial “risk”. In other words, the operator is also incentivized to increase commercial revenue and hence influence the service to a much higher degree in the form of improving service quality and punctuality. Finally, a last—not so frequent—type of contract could be viewed as a mix of the two previous contracts and is called the gross-cost contract with incentives. In this case, the operator still bears the production “risk”, and is levied some revenue “risk”. However, in the latter case, the incentives are lower than in a net-cost contract; the idea is to base some of the operator’s payment on a performance measure in order to get the operator to improve some aspects of the service. The estimation procedure considers again the same stochastic cost frontier as in [Battese and Coelli \(1995\)](#). The inefficiency index depends on several explanatory variables, namely, the population density of a contracting area, the ownership of the transport operator, a measure of the contracting term in numbers of years, and a dummy variable indicating whether the regulatory contract in place entails any incentive payment. An important assumption is that, since transport concessions are awarded through competitive tenders, more incentives in the form of a net-cost contract in place of a gross-cost contract without incentives may entail a higher “risk” for the operator. The latter may therefore require a risk premium in its bid in the form of a higher subsidy. Hence, incentives may lead to two opposite effects: The usual cost-reduction effect, which is the one on which most of the empirical literature focuses, and a cost-increase effect due to a risk premium, as emphasized here. More incentives could therefore lead to higher costs if the risk premium effect is large enough. The estimated results on the effect of the choice of contract are not significantly different from 0, which probably illustrates the fact that the ex ante risk premium impact emphasized by the author is not the unique effect to be expected in this case. The ex post effect, which guarantees that incentive contracts make the transport operator residual claimant for cost overruns and force the manager of the firm to provide a higher effort level to reduce costs, should be present as well. Since both ex ante and ex post effects go in opposite directions, it is not unreasonable that the estimation results show non-significant effect of the type of contract overall.

[Dalen and Gomez-Lobo \(2003\)](#) use the same estimation technique, but work on a slightly different regulatory context: They estimate a cost frontier model for a panel of Norwegian bus companies (1987–1997). Once again, their objective is to investigate to what extent different type of regulatory contracts affects company performance. On the one hand, regional authorities may bargain individually with transport companies on the subsidy levels to be granted during the forthcoming year; this arrangement should then be assumed to be of low power in terms of its incentive properties. On the other hand, a number of regional authorities have

adopted a more high-powered contract based on a yardstick benchmark, which consists in comparing similar regulated firms with each other: The regulator uses the cost of comparable firms to infer a firm's attainable cost target (Shleifer, 1985). This regulatory scheme is again similar in spirit to a fixed-price mechanism. In Norway the regulator and the transport operator agree upon a set of criteria for calculating the costs of operating a bus-network, namely, a cost index based on a linear model that links driver, fuel, and maintenance costs to the number of bus-kilometers produced for different categories of routes. Given fares and route schedules, this index determines the level of transfers that is granted to the operator. The important point is that the same standard cost model applies to all companies within a geographical area and transfers to the operator depend upon the cost performance of a large set of companies. The authors conclude that firms regulated under the yardstick type contract exhibit less than half the cost inefficiency compared to those firms regulated under the traditional contract, but they also acknowledge that contracts choice is endogenous, which complicates the interpretation of the results.

Similar estimation techniques are used by the following authors: Piacenza (2006) analyses a seven-year (1993–1999) balanced panel of 44 Italian municipal companies managed under cost-plus or fixed-price regulatory schemes. The stochastic inefficiency effects are supposed to be linearly related to the regulatory scheme and the commercial speed of the transit companies. The results confirm the initial hypothesis of a lower inefficiency under fixed-price schemes. Karlaftis and Tsamboulas (2012) use data from 15 European transit systems between 1990 and 2000 and test whether different efficiency assessment methodologies produce similar results and whether the impact of the contractual form are robust to the methodological specifications employed. They find that net cost contracts, where the operator bears both production and consumption "risk", involve higher efficiency indexes compared to the gross cost contract case where operators bear only production "risk". Margari et al (2007) focus on 42 Italian transport operators observed from 1993 to 1999. Their approach is based a three-stage methodology which mixes both data envelopment analysis and stochastic frontiers techniques in which they attempt to identify and separate three input-specific determinants of inefficiency, namely exogenous factors, pure managerial inefficiency and statistical noise. The so-called exogenous factors are related to the regulatory context and lie outside the managers' control but are direct decisions of regulators and policy-makers. It is found that the implementation of high-powered incentive contracts enhances production efficiency. The authors conclude that the main source for inefficiency has to be sought in contract choice or even random events, while pure managerial skills only play a minor role. Finally, an exception to all the results presented above is Zhang et al. (2018) which estimates transport efficiency for 26 different Chinese public transport operators in 13 cities across China for the period 2008–2014. Here contrary to previous predictions, the most powered incentive schemes do not entail the highest efficiency measures.

Contract Choice is Endogenous

The aforementioned studies assume that contract choice is exogenous, which is a potential drawback. As suggested for instance by Chiappori and Salanié (2003), contract endogeneity is an important issue since, in the presence of unobserved heterogeneity, the matching of transport operators to contracts is probably not independent from the unobserved heterogeneous firms' efficiency variables: If fixed-price contracts are given to efficient firms while cost-plus regimes are proposed to inefficient ones, the choice of contract is endogenous and any empirical analysis taking contracts as given will be biased. The 2.05% cost reduction emphasized in Gagnepain (1998) may not be caused by the implementation of fixed-price regimes but may illustrate instead a simple selection effect, that is, fixed-price contracts are chosen more often by efficient firms. Before turning to a presentation in the next section of a more structural analysis that allows to embody the endogenous effect in the structure of the cost expression to be estimated, we discuss in what follows a few proposals that attempt to address the endogenous bias in a reduced form.

Iseki (2010) addresses in part the endogeneity issue using data on the US bus transit services between 1992 and 2000. Transit agencies in charge of the organization of the service would typically implement three types of contracted service arrangements: 13% of the agencies contracted out a portion of service, while 21% of agencies contracted out for all service, and 66% contracted out no service. As emphasized by the author, assessing the effect of regulation on operating cost with a regression that combines contracting practices in several dichotomous variables may not be appropriate. The potential endogeneity problem is addressed by applying an instrumental variables technique which consists in predicting each agency's decision making regarding contracting: Two contracting categories are predicted using a multinomial logit model in the first-stage of the two-stage regression analysis which includes a set of explanatory variables related to agencies' revenue and governance characteristics such as labor conditions in the region, regional political climate, and state legislations governing regional and local governments. The results suggest that partial and full-contracting arrangements allow agencies to reduce operating costs.

Díaz and Charles (2016) focuses on the same French urban transport industry as in the previous studies (1995–2010). Efficiency is estimated in a first stage using a data envelopment analysis production frontier. In a second stage, the estimated efficiency indexes are regressed on a set of variables, including contract characteristics and a set of cities' fixed effects. The authors stress the role of unobserved heterogeneity in their analysis: If unobservable factors affect simultaneously both the efficiency and the choice of contracting types, a simple correlation analysis could be misleading. For instance, cities with geographical features that reduce the productivity of inputs might be the most interested in delegating the service to private firms or using certain type of contracts. The introduction of fixed-effects should at least solve the problem as long as the cities' unobserved characteristics are fixed over time, which may not be the case of congestion for instance. Moreover, unobserved characteristics on the operators' side could be relevant as well. Once again, fixed-price contracts are found to perform better than cost-plus contracts in terms of efficiency.

Auction Versus Negotiation

Before choosing a type of contract, such as fixed-price or cost-plus, a regulator must decide whether to organize a competitive tender in order to attract new firms and organize ex ante competition, or whether to negotiate the terms of a new contract with the incumbent. Such a decision has consequences as well on the future costs of the transport operator and the price paid by the regulator. The introduction of auction procedures in many developed countries aims at introducing competition for the field. An increase in the number of bidders should encourage more aggressive bidding, that is, lower bids. In a context of asymmetric information, it is well known from [Laffont and Tirole \(1987\)](#) that an optimal auction, which promotes reduces significantly the rent left to the operator compared to a situation in which a monopoly is regulated under an optimal second-best regime. In this section, we list a series of papers that attempt to provide empirical evaluation of these issues, keeping in mind that once again, regulatory arrangements are generally endogenous decisions, which complicates the analysis of the econometrician.

[Amaral et al. \(2013\)](#) investigate the relationship between the number of bidders and price reduction in the London bus market. They note that, even if competition among bidders leads them to reduce their bid, the winning bidder may, ex post, renege on the initial commitments. From an empirical perspective, this implies that assessing the impact of the number of bidders on price requires controlling for potential contractual renegotiations. The authors use a database on 806 calls for tender on London bus contracts (1999–2008) and find that a higher number of bidders is associated with a lower cost of service. A key issue is the potential endogeneity of the number of bidders, as the expected value of the winning bid potentially influences the number of participating bidders or both variables may be jointly affected by a third variable, such as the value of the service for instance. In order to get rid of potential time-varying heterogeneity, the authors add in the regression the number of auctions organized during the month as well as the number of auctions already won by the winner during the previous month. The estimation results confirm a positive and significant cost-reducing effect of competition.

[Scheffler et al. \(2013\)](#) investigates the impact of the introduction of competitive tendering in German public bus transport networks. Over the period of observation (2004 to 2009), Germany's public bus transport markets remain dominated by publicly owned companies that provide services based mainly on monopoly rights without competitive tendering. In 2009 a large majority of bus operators were fully publicly owned. European regulation (EC) No. 1370/2007, which came into force at the end of 2009 specifies that local authorities have the right to award services directly to transport companies which are under the actual control of the local authority. A direct award is also backed by EU law if the size or value of the transport service contract is small. Hence, German local authorities can generally decide on a discretionary basis as to which services they wish to open up to more competition. The methodology chosen by the authors consists in estimating a production stochastic frontier, as proposed by [Battese and Coelli \(1995\)](#), where the inefficiency term depends on a dummy variable that takes value 1 if the bus operator is chosen under a competitive tendering procedure. Once again, regulatory endogeneity is a potential issue here. Local authorities can generally decide on a discretionary basis as to which services they wish to open up to more competition. A local public might decide to open a route to competition if the publicly owned incumbent is already relatively efficient, and therefore likely to succeed in the tendering process. To address this issue, the authors use as a benchmark the Federal State of Hesse, where local authorities were obliged to put routes out to tender from 2002 to 2007; hence services tendered in this period in this area were not subject to regulatory discretion. Estimation results suggest that there is no significant difference on the influence of technical efficiency between competitive tendering in general and competitive tendering in the Federal State of Hesse, which allows the authors to discard the issue of endogeneity. Bus companies which operate in areas where competitive tendering takes place are more efficient than others. A somehow analysis is provided by [Filippini et al. \(2015\)](#) but the conclusions differ: The authors focus on 630 bus lines operated by the main Swiss company, Swiss Post, in 2009 throughout the country. Following the revision of the Swiss railways act in 1996, regional public authorities were given the choice between two different contractual regimes to procure public passenger transport services, competitive tendering versus negotiation. The paper evaluates the impact of competitive tendering and performance-based negotiation using a stochastic frontier analysis. About 10% of Postbus lines have gone through a competitive tendering process between 2005 and 2015. The estimation results show that the average levels of cost efficiency are relatively high and no significant differences are observed between competitive tendering and performance-based negotiation.

Moreover, [Mouwen and van Ommeren \(2016\)](#) aims at assessing the impact of contract renewal and competitive tendering on operational costs. They employ a panel dataset for the period 2001–2013 on the level of concession areas in the Netherlands. Contract renewal allows several operators to bid for a new contract. More precisely, in the period under study, 61 contract were renewed and 69% of these were renewed after a process of competitive tendering of which about half were awarded to a new operator. The authors estimate a cost function, which accounts for the number of contract renewals between 2001 and the period of observation. They find that contract renewal leads to a substantial reduction in operational costs: When a contract is renewed at least once, costs fall by 10%, while contracts renewed at least twice even lead to an extra costs reduction of 6%.

To conclude this section, note that the endogeneity of the decision of whether a service should be tendered or not also depends on the importance of transaction costs in the industry. [Bajari et al. \(2008\)](#) suggest that auctions perform poorly when projects are complex and contractual design is incomplete. [Hensher and Stanley \(2008\)](#) suggest that there may be high transactions costs of retendering through competitive processes, causing ex post adaptation to become an important feature of the transaction. Properly structured transparent and performance-based negotiated arrangements may avoid this problem and protect the provision of service, while meeting government service objectives. Performance-based negotiation can also avoid some drawbacks of competitive tendering, such as asymmetric information, lack of trust, and hold-up problems between the incumbent and the public authority.

Finally, [Yvrande-Billon \(2006\)](#) also suggests that problems associated with competitive tendering come from the contractual disabilities of the parties.

Structural Models

The treatment of contract choice endogeneity in reduced forms analyses such as the ones presented in the previous section typically require a two-step (sequential) estimation procedure where the inefficiency index for each transport operator is estimated first, and is then regressed on the set of contract characteristics. We turn now to more structural models which intend to embody directly in the structure of the functional form to be estimated the incentive impact of the observed contract impinging on the activity of the transport operator.

We explain briefly how the structural cost expression is constructed, starting with [Gagnepain and Ivaldi \(2002a\)](#). We consider a Cobb–Douglas technology:

$$Y = A \prod_{j=1}^n X_j^{\alpha_j} \exp[e - \theta + \epsilon_Y]. \quad (1)$$

with one output Y and n variable inputs X_j , where A and the α_j 's are parameters describing the technology. To construct the dual cost frontier, we assume that the producer seeks to minimize the cost C of producing its desired rate of output Y under technical inefficiency. The associated allocation of inputs sets the factor demand X_j , $j = 1, \dots, n$. The program of the producer is then as follows

$$\min_{X_j} \sum_{j=1}^n w_j X_j, \quad (2)$$

under the previous technological constraint, where w_j is the price of input j . The excess of factor demand above its frontier prevents the producer from reaching the theoretical level of production. Such a distortion of factor demands leads to a rise of operating costs. In logarithmic form, the associated stochastic cost frontier, $C(Y, w, e, \theta)$, is given by

$$\ln C(Y, w, e, \theta) = K + \sum_{j=1}^n \frac{\alpha_j}{r} \ln w_j + \frac{1}{r} \ln Y + \frac{\theta - e}{r} + \epsilon_c, \quad (3)$$

where $r = \sum_{j=1}^n \alpha_j$ measures returns to scale, and K is a constant. Note that the term $(\theta - e)/r$ is the total cost distortion above the cost frontier. Global inefficiency is smaller when the industry enjoys large returns to scale r . This cost frontier expression is preliminary as the cost reducing effort e is endogenous and depends on regulatory schemes or the competitive environment set by the regulator. We turn now to the cost reducing activity aspect of the problem. Consider a transport operator whose profit function is

$$\pi = R(Y) - C(Y, w, e, \theta) - \psi(e), \quad (4)$$

where $R(Y)$ denotes its revenue. Exerting effort is costly and leads to internal cost $\psi(e)$. A profit-maximizing operator determines the optimal effort level. The first order condition is given by $\psi'(e) = -C_e$, which states that the optimal effort level is chosen to equalize the marginal disutility of effort and the marginal costs savings. Let us define a specific functional form for the internal cost of effort $\psi(e) = \exp(\tau e) - 1$, where $\tau > 0$. The first order condition on the effort can then be expressed using the cost frontier and the internal cost of effort. The level of endogenous effort exerted by the operator is obtained as $e = e(K, w_j, Y, \theta, \tau, \alpha)$, and is then reintroduced in the preliminary frontiers in order to derive the final structural cost frontier to be estimated:

$$\ln C = H_C + \xi \left[\sum_{j=1}^n \frac{\ln w_j}{r} + \frac{1}{r} \ln Y - \frac{\alpha_k}{r} \ln k + \frac{1}{r} \theta \right] + \epsilon_C, \quad (5)$$

where H_C is a constant and $\xi = \tau/(\tau + 1/r)$. If the effort of the producer is nil, the structural cost frontier is given by the expression:

$$\ln C = K + \sum_{j=1}^n \frac{\ln w_j}{r} + \frac{1}{r} \ln Y - \frac{\alpha_k}{r} \ln k + \frac{1}{r} \theta + \epsilon_C, \quad (6)$$

[Gagnepain and Ivaldi \(2002b\)](#) use a database on the French urban transport services described above. The panel data set covers 59 different urban transport networks (operators) over the period 1985–1993. We stressed earlier that two types of contract are observed in practice, cost-plus and fixed-price schemes. The empirical work involves fitting the stochastic cost functions presented in Equation (5) and Equation (6) to this data set. Under fixed-price regimes, we would estimate Equation (5), while we would estimate Equation (6) under cost-plus contract.

The estimation of the system (5) and (6) allows recovering individual inefficiency and effort indexes for each local transport operator. **Table 1** lists the estimated technical inefficiency, effort levels and cost distortions over the frontier for the biggest networks included in the dataset. **Fig. 1** provides for each network, the level of the inefficiency parameter and indicates the type of contract

Table 1 Technical inefficiency, effort level, and cost distortion for some networks

Figure 1 Inefficiency and regulatory schemes. To each network are associated three data: the inefficiency level (white bar), the cost distortion (black bar) and the type of contracts (a black diamond refers to a fixed-price contract and an empty circle indicates a cost-plus contract). Source: Based on Gagnepain and Ivaldi (2002b)

used to regulate it. Note that three groups of networks are easily detected. The first group with the lowest levels of cost distortion gathers sixteen networks, all of which are managed under a fixed-price contract. The next twenty ones can be collected in a second group as all of them (but four networks) are regulated through a cost-plus contract. Finally the last twenty networks are assembled in

a third group, almost equally shared between the two types of contract. Concerning the third group, we just conclude that technical inefficiency is so high that even a highly incentive scheme, such as a fixed-price contract, cannot cure the problem. This structural methodology has been tested successfully in other industries such as, for instance, the Norwegian bus industry (Dalen and Gomez-Lobo, 1997) or the European railroad industry (Urdanoz and Vibes, 2013).

The question of how contracts are chosen and how the information can be included in the estimation process is important and is discussed in Gagnepain and Ivaldi (2017). On the one hand, the choice of contract is determined by its impact on welfare. Welfare, however, is in turn also determined by the contract choice, which implies an endogeneity between the changes in welfare and the contract choice. To address this issue, the authors estimate a structural endogenous switching model where the welfare expression depends on the choice of contract and vice versa. In the model, a regulator chooses the regulatory mechanism (a fixed-price or a cost-plus contract) that maximizes an extended welfare function that entails the usual social welfare measure plus additional weights allocated to specific interest groups. The interest groups are the workers and the stakeholders of the regulated firm. The regulator overstates the weight of one group or another through workers' wages or firms' profits, and this creates a distortion of the regulatory contracts toward less or more powerful incentive schemes. Simultaneously, the regulatory rule affects the operator's behavior and the operating costs in one way or another. It is shown that a simple structural cost function, which does not account for the choice of contract is rejected against the political model advocated in this paper. Hence, accounting for the contract choice turns out to be adequate and fruitful, since it improves the quality of the estimates. The results suggest that ignoring the process of contract choice yields estimates that undervalue the importance of regulatory incentives for the operator's activity.

Gagnepain et al. (2013) extends this analysis into a dynamic setting. In the French urban transport industry, contracts are usually signed for 5 years periods and an extended enough database (1987–2002) allows the econometrician to observe series of contracts in the same local transport network over several periods. Interestingly, a dynamic perspective sheds light on the fact that the power of the incentives of a specific contract and the cost inefficiency type of the transport operator who chooses a specific contract are strongly related. This paper shows that very efficient firms choose series of fixed-price contract over time while very inefficient ones prefer series of cost-plus contracts. In-between, firms that are neither very efficient nor very inefficient choose a cost-plus arrangement first and switch to a fixed-price regime only if subsidies are increased.

Conclusion

This chapter focuses on the assessment of the impact of contractual regimes on the efficiency of public transport operators. The economic literature is almost unanimous on the fact that the incentive power of the contracts used by public authorities in charge of the organization of the service does indeed have a significant effect on the firms' costs. In particular, fixed-price contracts, which entail the highest possible incentive power, and which are very often implemented in the transport industry, are the ones that encourage operators to reduce their operating costs the most.

The issue of the measure of the magnitude of these effects remains, however, quite tricky to deal with since, as we have consistently pointed out in this chapter, a potential issue of selection linked to the choice of contract can create significant biases in the estimation results. The approaches used to address these biases have so far been of two types. First, in studies based on the estimation of reduced forms of cost functions, the authors choose to perform a two-step identification in which efficiency is first measured using a cost or a production frontier, and is then regressed on a set of variables that shed light on the characteristics of the productive environment. Structural studies allow integrating directly in the body of the function to estimate the structure that accounts for the contractual framework and that allows identifying the endogeneity bias.

Using incentive contracts can therefore encourage transport operators to reduce their costs. But it is also important to remember that the optimal nature of these contracts is economically guaranteed if the incentive power of each contract is adjusted to the productive efficiency of the transport operator. In other words, a fixed-price contract must be offered to a very efficient company while a cost-plus contract must be offered to a very inefficient company. Naturally, other types of contracts with intermediate incentive powers could be designed for operators characterized by average efficiency levels. The ability to design these contracts together with a good assessment of the volume of subsidies to be paid to operators (in order to avoid giving those too large rents) depends on the expertise capability of the public authorities. The role of the economist in this context is then to also encourage these authorities to equip themselves with adequate resources in order to implement the sometimes-sophisticated tools proposed by economic research.

Introduction

Company cars, sometimes also called “benefit cars” or “take-home cars” (Engström et al., 2019), now represent a significant share of national car fleets. Cohen-Blankshtain (2008) suggests that company cars account for 10%–50% of car fleets in different countries. Company cars are usually justified as a necessary means for conducting a job requiring travel, for which a vehicle needs to be made available. More regularly, reasons for company car provisions may be tax benefits that exceed the cost of an equivalent monetary remuneration. As only a share of the taxable benefit of a company car is actually taxed, this is a financially beneficial model for companies, company car recipients, as well as car manufacturers. Company cars are a form of subsidy forwarded to consumers and producers in the automotive system.

Even though there is a considerable body of literature on company cars, it is notable that no discussion of the history of company cars is available. It seems that company car benefits were initially forwarded only to individuals at the top of companies as a form of additional financial benefit: the share of income spent on the car is significant throughout the world. Today, company car benefits are mainstreamed, with estimates that 50% of all new car registrations in the European Union are company cars (Nss-Schmidt and Winiarczyk, 2009).

Company Car Benefits

Company cars represent a subsidy forwarded to employees and company owners, because they are often used privately, or by other household members, without being fully taxed in theory and/or practice (Harding, 2014). For this reason, the fiscal and environmental implications, such as foregone tax revenue or environmental impacts, have been featured prominently in a wide range of publications (Dargay et al., 2007) and official documents by the European Union, OECD or other supranational organizations (Gutiérrez-i-Puigarnau and van Ommeren, 2011; Princen, 2017; Ramaekers et al., 2010; Shiftan et al., 2012; Van Ommeren et al., 2006; Graus and Worrell, 2008).

The legal and fiscal basis for the provision of company car benefits is that work-related travel is tax-deductible (Cohen-Blankshtain, 2008). As private trips are not related to income generation, they represent a personal benefit where they remain partially untaxed (Harding, 2014). Even though most countries do have rules regarding the private use of company cars, there is much evidence that a significant share of the cost associated with private travel is covered by employers. This would include items such as the cost of car registration, insurance, maintenance, and repairs, which private car owners have to pay for themselves; as well as fuel and operating expenses, with evidence that where these aspects are taxed, this only represents a share of the value in question (Harding, 2014).

Table 1 provides a typology of tax rules regarding the private use of company cars in OECD countries (Harding, 2014). Such taxation principles have followed a wide range of different approaches. For instance, in Spain or Switzerland, taxation is based on the consideration of the percentage of capital cost compared to cost price; in Belgium or Norway, in comparison to list price; in the United States, in comparison to fair market value. Other countries including Canada or Luxembourg consider the distances traveled for private purposes, or they consider the direct cost that may be private (Australia, Japan) vis-à-vis business related (Austria, South Africa). Finland and Sweden have lump sum approaches; Hungary and Mexico do not tax company cars at all.

Notably, commuting to work is considered a tax-deductible expense only in some countries, and even where approaches to taxing company car benefits are identical, there are often considerable differences. For example, in Germany, the recipient of a company car has to tax 1% of the list price of the car (Metzler et al., 2019), whereas in Israel, the list price tax is more than twice as high (Shiftan et al., 2012). An important implication of most taxation approaches is that the higher the car’s value, or the more the car is used, the greater is the benefit to the employee (Diekmann et al., 2011; Metzler et al., 2019).

There is a general consensus in the literature that company cars represent very significant subsidies forwarded to employees. For example, Diekmann et al. (2011) estimate that the untaxed company car benefit in Germany is worth an annual €3.3–5.5 billion. A

Source: Based on [Harding \(2014\)](#)

study in Belgium the value of lost tax revenue at €3.75 billion per year, or 0.9% of the country's GDP ([Princen, 2017](#)). Another calculation for the Netherlands estimated the welfare cost of company car taxation at €2000 per car ([Gutiérrez-i-Puigarnau and van Ommeren, 2011](#)). An estimate for the European Union ([Ness-Schmidt and Winiarczyk, 2009](#)) concludes that undertaxation is a norm throughout the region, with direct revenue losses in the order of €54 billion per year, and distortions of consumer choices adding annual losses of €12 billion to €37 billion. A study of 26 OECD countries, [Harding \(2014\)](#) concluded that untaxed benefits were equivalent to a weighted average subsidy per company car in the order of €1600 per year, corresponding to an estimated €26.8 billion. Only 44%–58% of the benefits forwarded to employees are taxed in the OECD. There is thus overwhelming evidence that company car benefits represent a very significant subsidy, and on a global scale.

Observed Changes in Transport Behavior

Company car benefits change travel behavior and wider choices pertaining to the car. Most of these changes are linked to real or perceived benefits associated with company cars, and can be summarized as being related to transport mode preferences, car model choices, car availability and endowment, travel behavior, driving styles, and interest in alternative fuel technology. These changes and their implications are presented in [Table 2](#).

As an example for transport mode choice, various authors have outlined that company car availability automatically turns the car into the self-evident transport choice, to the detriment of other transport modes such as bicycle, bus, tram, or train ([Dargay et al., 2007](#); [Harding, 2014](#); [Ramaekers et al., 2010](#); [Shiftan et al., 2012](#)). Various studies have also found that company cars are regularly larger and more fuel consuming than private cars ([European Commission, 2002](#); [Graus and Worrell, 2008](#)). In light of

Table 2 Overview of changes in transport behavior induced by company car

Aspect	Change	Implication
Transport mode	Car use vis-a-vis modal split (bicycle, bus, tram, train)	Car use becomes habit and sole transport mode
Car model choice	Larger cars are provided than would have been bought by employee privately	Car size and motorization increase, as well as specific fuel use
Car age and efficiency	Company cars are newer and thus less energy consuming	Company cars change fleet age positively, are more efficient
Car availability	Other family members use company car	Car availability and perceived low cost generate additional transport demand
Car endowment	Second private car becomes affordable	Two cars increase opportunities for automobility
Travel behavior	Car use increases as a result of lower (perceived) cost	Transport demand increases
Driving style	Driving style less energy efficient as a result of lower (perceived) cost	Specific fuel use increases
Fuel use	Significantly more fuel is used by company car drivers	Overall fuel use increases
Interest in alternative fuel technology	Powerful cars with combustion engine represent norm	Attachment to cars with combustion engines grows, while other technologies become less attractive

recent research, fuel use is a more complex issue: for example, data for Germany suggest that company cars are significantly newer (4.4 years) than private cars (7.6 years) (Metzler et al., 2019). Even though company cars are more heavily motorized, at 97 kW (compared to 79 kW for private cars), fuel use was found to be almost identical to private car consumption, at 7.77 L/100km (compared to 7.80 L/100km for private cars). It is unclear, however, if fleet average fuel consumption would be lower if the fleet age was higher, yet consist of smaller and more efficient cars; this could be the case in a scenario where company car benefits did not exist.

Company cars also affect household car ownership patterns. In a study of Israeli company car owners, 64% had two cars; that is, more than the average household, suggesting that company cars are considered a saving that makes an investment in a second private car more likely (Shiftan et al., 2012). This was statistically tested in a German study (Metzler et al., 2019). Results suggest that company car households have an average of 2.0 cars, while households with private cars own an average of 1.6 cars. The study concluded that company car benefits increased household car ownership by 25%.

Travel behavior is one of the best studied variables in the context of company car ownership, and it has been suggested for decades that company cars will make employees more willing to accept longer commutes (van Ommeren et al., 2006). Quantitative studies have shown company cars to be driven 100%–200% more than private cars (Graus and Worrell, 2008; Johansson-Stenman, 2002; Ramaekers et al., 2010). Metzler et al. (2019) showed that company cars in Germany are driven an average 24,672 km per year, compared to 12,828 km per year for private vehicles. Only part of these greater distances is associated with work (Shiftan et al., 2012), as company car ownership stimulates the transport demand of other household members and increases the likelihood of leisure trips (Shiftan et al., 2012).

As perceptions of fuel use being either free or at least less costly, company car drivers have also been found to have more wasteful driving styles, characterized, for example, by idling, higher speeds, hard acceleration, or deceleration (Rutty et al., 2013). Driving styles, and in particular the greater distances traveled, translate into greater fuel use. Owners of company cars in a study in German consumed an average 1170 L of gasoline or 2361 L diesel per year, depending on the respective cars' engine type. Corresponding values for private car owners were significantly lower at 830 L (gasoline) and 1157 L (diesel) per year (Metzler et al., 2019).

Finally, company cars also have implications for the interest in alternative fuel technologies, such as electric engines or fuel cells, though outcomes are partially contradictory. Research in the Netherlands (Koetse and Hoen, 2014) found that company car drivers preferred conventional combustion engines, as a result of more limited driving ranges, recharge times, and refueling infrastructure limitations. Hybrid and flexifuel cars were perceived as more suitable for company car driver needs, and electric and fuel cell cars were more commonly bought by drivers with low mileage. Engström et al. (2019) found that company car drivers did prefer alternative fuels to combustion engines, though these choices also resembled larger, more heavily motorized and expensive cars.

Environmental Outcomes

As has been repeatedly highlighted in the literature, the existence of company car benefits has a wide range of social, economic, and environmental implications (Whitelegg, 1984). Company cars are often driven by high-income takers (Börjesson and Kristoffersson, 2018), and tax benefits thus mostly accrue to the upper income classes. This is particularly relevant in the context of climate change and emissions from transportation, as there is growing evidence that there are very significant differences in individual contributions to climate change. As highlighted in the preceding section, company cars initiate and support behavioral change and transport choices that contradict societal goals regarding accidents, space requirements for transportation, noise, air pollution, as well as climate change mitigation.

Climate change stabilization is the most important international environmental goal. The Paris Agreement focuses on stabilizing temperatures at a maximum increase of 2°C, compared to preindustrial levels, and foreseeing steep cuts in emissions. Transportation contributes about 23% to total global energy-related CO₂ emissions, and almost three quarters of transport emissions (72.1%) are caused by road transport (IPCC, 2014). How frequently vehicles are used, and which energy intensity these vehicles have, is thus of central importance for emission outcomes. Few studies have investigated the impact of company car benefits for all changes in vehicle choices and travel behavior. In one study for Germany, Metzler et al. (2019) found that private car owners emitted 2.0 t to 3.0 t CO₂ per year, while the corresponding amount was 2.8 t CO₂ to 6.2 t CO₂ for company car drivers. A significant share of the difference can be assumed to be a result of company car benefits, though it is difficult to determine the exact difference.

Conclusions

Company cars represent a form of subsidy forwarded to drivers and companies, who may seek to compensate employees indirectly with car-related benefits. Company cars are also a subsidy to car manufacturers, as they increase the number of cars per household. As specific car types are in higher demand - more powerful, larger, and expensive cars -, company car benefits also support the development of specific car model markets. These concerns over company cars have been raised for decades, with authors (Börjesson and Kristoffersson, 2018; Metzler et al., 2019) and organizations calling for reform (Harding, 2014).

There is no shortage of specific recommendations regarding the design of such company car tax reforms. Proposals have included limiting company car numbers (Cohen-Blankshtain, 2008), as well as changes in taxation, specifically with regard to private use (Shiftan et al., 2012). In practice, none of these changes will lead to a situation in which foregone tax revenues are recaptured, and they are unlikely to prevent other negative outcomes of tax benefits. In most countries, there is a simultaneous lack of equal

treatment of company cars with forms of micromobility; this is, while (private) automobility is deductible, it is impossible to deduct taxes for walking, carpooling or bicycling. This is relevant, because automobility represents a social cost, while bicycling or walking constitutes a benefit (Harding, 2014). It has thus been suggested that bicycling should be rewarded economically, while commuting by car should not be tax deductible at all (Laine and van Steenberg, 2017).

It is evident that transport demand can be reduced by eliminating the preferential tax treatment of company cars (Börjesson and Kristoffersson, 2018; Metzler et al., 2019). In view of the changes in car model choice and transport behavior, and the limited effects of company car purchases in terms of introducing alternative fuels, it seems difficult to see company cars in any other way than an overcame tax relief forwarded to car manufacturers, companies and drivers. All studies on company car externalities conclude that such tax reliefs are no longer timely. Even though no estimate of the global scale of the company car tax relief has been published, it is fair to assume that it is significantly higher than the €66–€91 billion calculated by Nass-Schmidt and Winiarczyk (2009) for the European Union.

As any change in company car benefit structures will affect many people, and with significant monetary losses, resistance to policy change will be significant. Notably, company car benefits are perceived as more attractive than additional pension payments, life insurances or savings plans (Macharis and Witte, 2012). However, in light of the negative externalities incurred by company cars, such change is paramount. Abolishing company car policies will lead to changes in transport systems that would include greater interest in alternative transport modes, smaller cars, and new mobilities. These are associated with further reductions in negative externalities, such as the very significant health cost of air pollution (Lancet Commission, 2017).

Environmentally, an elimination of company car benefits also has importance for climate change mitigation. Where CO₂-based vehicle taxes or the taxation of emissions are combined with the abolishment of company car benefits (Dineen et al., 2018), these two measures alone could bring EU (and worldwide) passenger transportation back on track to achieving the climate mitigation goals as outlined in the Paris Agreement. Currently, there is very limited evidence of climate policies for road transport that will change the status quo. Overall, findings thus suggest that irrespective of perspective—social welfare, environment, and even business economics—there is thus no good reason to maintain company car tax benefits.

What are Transportation Network Companies (TNCs)?

Transportation network companies (TNCs) (also known as ridesourcing and ridehailing) provide prearranged and on-demand transportation services for compensation, which connect drivers of personal vehicles with passengers (Shaheen and Cohen, 2019). Smartphone applications are used for booking, ratings (for both drivers and passengers), and electronic payment. TNCs can provide both nonpooled (e.g., single-passenger) and pooled services (e.g., multiple passengers), which are referred to as ridesplitting. Ridesplitting is a type of TNC service that involves volunteering to share a for-hire ride with someone at a reduced cost (Shaheen and Cohen, 2019). Volunteering to split a ride typically includes a discount and may or may not result in a shared ride depending on demand and the origin/destination match suitability. TNCs differ from carpooling and vanpooling (also known as ridesharing) in its financial motivation; carpooling is not intended to result in a financial gain. TNCs also differ from taxicab services as taxis are permitted to pick-up street hails, where TNCs are not permitted to do so in most jurisdictions. Additionally, while taxis are often regulated to charge static fares, TNCs often use variable market-rate pricing, which can also employ “surge pricing” in which prices go up during periods of high demand to incentivize more drivers to take ride requests. Additionally, TNCs typically provide the traveler with an established fare at the beginning of a trip whereas taxis can employ either fixed pricing (e.g., an agreed upon fare between the passenger and the driver, zone-based pricing, etc.) or variable pricing (e.g., meters) where the actual cost of a journey is unknown to the passenger until the trip is complete. A common critique of metered pricing is that it can be susceptible to driver manipulation, such as “long hauling” (where a driver takes a more circuitous route to increase the fare) or “zapping” (an attachment to a taxi meter or its wiring system that illegally boosts mileage and customers’ fares during trips). As such, for-hire services that provide consumers with an established price when a traveler commences their journey, such as TNCs, taxi e-Hail, and zone-based pricing tend to offer consumers greater transparency and protection against fare manipulation. Services provided by TNCs vary in terms of the number of drivers available on the platform, geographic span, prices charged customers, and available services. Some may provide specialized services for particular market segments (e.g., services for children, older adults, people with disabilities, etc.). In addition to providing traditional for-hire services that connect customers requesting rides to drivers of cars, some TNC companies also provide bikesharing, scooter sharing, and courier network services or flexible goods delivery on their platforms. This chapter focuses on the impacts of for-hire passenger services offered by TNCs.

In recent years, TNCs have grown rapidly due to technological advancements, changing mobility patterns, and evolving perspectives toward transportation and vehicle ownership. TNCs may be able help bridge gaps in the transportation network (e.g., facilitating first- and last-mile connections to public transit, offering late-night transportation, and services scaled for lower-density communities). As such, TNCs may be able to help bridge gaps in the public transportation network by extending geographic coverage and the operating times of public transit services. Additionally, more modal options and a larger pool of travelers can create a “network effect,” where mobility options in close proximity to one another add collective value. This network effect may also be able to support pooled TNC services, sometimes referred to as ridesplitting or pooling. Ridesplitting involves a person sharing a TNC vehicle and splitting the cost of a ride with someone else taking a similar route.

TNC Impacts on Travel, Labor, and Emissions

Studies on the impacts of TNCs are emerging and have been shown to have varied impacts on vehicle miles traveled/vehicle kilometers traveled (VMT/VKT), modal choice, automobile ownership and use, and public transit ridership, which are typically

impacted by local characteristics such as: urban density, the built environment, public transit accessibility, public policy, and other factors (Aleml et al., 2018; Brown and Taylor, 2018; Clewlow and Mishra, 2017; Feigon and Murphy, 2018; Hampshire et al., 2017; Henaio, 2017; Martin et al., 2020). TNCs can have some of the following impacts:

- Increasing access and mobility for nonvehicle owners;
- Increasing for-hire vehicle service availability, particularly in the evening and on weekends and in smaller markets where taxi service is limited or unavailable; and
- Affecting labor in various ways, such as increased employment opportunities and uncertain financial impacts on drivers (e.g., opportunities for new drivers, downward wage pressure on existing taxi drivers, tax implications with respect to employee versus independent contractor relationships, and worker benefits).

TNC impacts on vehicle trips and occupancy, VMT/VKT, greenhouse gas (GHG) emissions, and other transportation modes can vary as well. TNCs produce VMT/VKT and associated GHG emissions when driving to an area with passenger demand, deadheading while awaiting a ride request, heading to pick up a passenger, and completing the ride itself. TNCs can also reduce VMT/VKT and GHGs through behavioral change, such as passengers who decide they no longer need to own a car due to TNC availability. TNCs can also have substitutive effects on existing transportation modes, such as changes in active and public transportation use. A three-city study of TNCs in Los Angeles, San Francisco, and Washington, DC found that VMT produced by TNCs was larger than the VMT reductions that occurred due to passenger behavior and vehicle ownership change in Los Angeles and San Francisco. However, in Washington, DC, the study found that the balance of impacts resulted in a net VMT and GHG reduction, which is likely due to land use and the built environment, including public transit availability and urban densities. The study also found that pooled TNC services can mitigate TNC VMT and emissions; however, this impact is highly sensitive to match rates and mode substitution (Martin et al., 2020). Pooled and privately used TNCs may be drawing from a slightly different cross-section of travelers, with pooled TNC services drawing more heavily from public transit and private TNC services. It is important to note that single passenger (not pooled) TNC services are more likely to substitute passenger vehicle modes (e.g., a personal vehicle, taxi/E-hail taxi, or carsharing vehicle). Research on TNC impacts varies based on a variety of factors such as: the built environment, public transit accessibility, urban density, and other city-specific factors. TNC studies tend to suggest that they may be drawing more people from public transit in denser cities, a phenomenon sometimes referred to as peak shedding. In less dense cities, studies indicate that TNCs more often replace private automobile trips. It is important to note that aggregated cross-city studies run the risk of obscuring city-specific differences in TNC impacts. In addition, if respondents are asked what transportation mode they would generally take in contrast to TNCs (instead of what mode they would have used for their last TNC trip), responses may be less representative of a respondent's mode replacement decision.

TNCs and Curbside Management

TNCs, depending on passenger demand and locations served, may require frequent loading and unloading of passengers. When there are not designated pick-up and drop-off locations, vehicles may stop in the roadway, shoulders, on-street parking, bike lanes, and public transit stops, which can lead to congestion, modal conflicts, and safety hazards. A number of public agencies are developing policies to establish loading zones for shared modes, such as TNC vehicles. For example, Washington, DC has established nightlife zones designated for TNC passenger pick-up and drop-off between 10 p.m. and 7 a.m., Thursday night through Sunday morning.

TNCs and Social Equity

Similar to other forms of shared mobility, TNCs can be associated with social equity challenges. Many TNC studies have examined who uses the service, when, and for what purposes. Research suggests that TNC users tend to be younger, of higher income, and with higher levels of educational attainment than the general population. TNC passengers also tend to have lower vehicle ownership rates, commute using public transit at a higher rate, and are less reliant on single-occupant vehicles for commuting. A number of studies have documented higher TNC usage on evenings, weekends, and during weekday peak periods (e.g., 7 to 11 a.m. and 5 to 9 p.m.). Restaurant/bar, social/recreational, and commuting are commonly indicated trip types.

A number of studies have suggested that TNC drivers may engage in unauthorized and prejudicial behavior such as: driving female passengers on longer than needed trips between origins and destinations (e.g., to engage in conversations to get a passenger's personal information, such as a telephone number or workplace, and/or to make unwanted verbal or physical sexual advances) and rejecting or canceling riders with minority sounding names. Six common transportation equity challenges include:

1. Affordability: "It's too expensive."
2. Predictability: "Will dynamic or surge pricing make it too expensive?"
3. Availability: "The services aren't available in my neighborhood."
4. Payability: "I don't have an acceptable payment method."
5. Accessibility: "The service isn't accessible for my medical condition."
6. Techno-ability: "I don't have a smartphone or a data plan."

Generally, these challenges can be categorized into four overarching themes:

1. **Access for People with Disabilities:** TNCs may not always provide wheelchair accessible services or be available in all markets.
2. **Un- and Under-Banked Households:** TNCs generally require debit/credit cards for payment. This can be a barrier for consumers who are under-banked or unbanked. TNCs may be able to provide alternative fare payment options to help overcome this.
3. **Low-Income Affordability and Service Equivalency:** TNC pricing can be expensive compared to other modes, particularly during periods of high demand and low supply (known as surge pricing).
4. **Digital Poverty:** TNCs typically require a smartphone and high-speed data package to access services. This can be a barrier to low-income and rural households who may not be able to afford or may lack data coverage to access TNCs. Alternatives such as digital kiosks, telephone services, and nontech access (such as street hail—that are generally prohibited by TNCs in most jurisdictions) can help overcome these challenges.

Future of TNCs and Vehicle Automation

Many experts predict the convergence of shared modes; mobile services (e.g., smartphones and wireless data); electrification; and automation. This convergence will further transform taxis, TNCs, and pooled service options. In particular, vehicle automation will be one of the most transformative developments in automotive history, as it is deployed over the coming decades. SAE International, a global mobility standards organization, has established five levels of vehicle automation. Level 1 describes vehicles that automate only one primary control function (e.g., self-parking or adaptive cruise control). Level 2 describes a vehicle with automated systems that have full control of specific vehicle functions such as, accelerating, braking, and steering. With Level 2, the driver must still monitor driving and be prepared to immediately resume control at any time. Level 3 allows the driver to engage in nondriving tasks for a limited time. With Level 3, the vehicle will handle situations requiring an immediate response; however, the driver must still be prepared to intervene within a limited amount of time when prompted. With Level 4, a human operator does not need to control the vehicle as long as the vehicle is operating within the specific conditions the vehicle was intended to function. Level 5 describes vehicles that are capable of driving in all environments without human control. By automating driving tasks, shared, automated, electric mobility services could become much more cost effective, efficient, and convenient than human-driven, privately owned vehicles. These studies predict vehicle automation and electrification, coupled with pooling, will result in shared automated vehicles (SAVs) that offer for-hire services that are less expensive on a per mile basis than privately owned vehicles (Greenblatt and Saxena, 2015). These studies suggest notable cost savings in three key areas: (1) labor cost savings associated with no longer needing a driver; (2) energy cost savings associated with electrification; and (3) cost savings associated with pooled rides (e.g., sharing fares among passengers with similar origins and destinations). Operationally, the cost savings coupled with the convenience of SAVs, pickup, drop-off, self-parking, and self-charging could be a driving force toward reducing private-vehicle ownership (particularly if coupled with curb management, street design, and pricing policies).

Many companies are beginning to explore the concept of shared and fully automated fleets. Cities and public agencies have recently begun to examine the possibility of managing SAV services. While it is too early to predict the range of service types that may exist as part of a SAV ecosystem, new vehicle types and services will develop over time. SAVs have the potential to reduce vehicle ownership and provide innovative opportunities to lower cost and offer flexible service models such as: (1) closed campus applications (e.g., business parks); (2) first- and last-mile connectivity; (3) low-density service; (4) off-peak/late-night service; and (5) paratransit services. SAV business models, along with passenger capacity, will shape their impacts.

Possible Impacts of Shared Automated Vehicles

While SAV impacts remain uncertain, many practitioners and researchers predict higher efficiency, affordability, and lower GHG emissions. A few studies have found that wait times could lower willingness to switch to SAVs, and marginal increases in cost also affect the likelihood of using pooled SAVs. Some hypothesize that traditional taxis in urban areas may be the first transportation mode to be replaced by SAVs. As such, automation could increase the ease of multimodal connections to public transit facilitated by SAVs (first and last mile). However, SAVs could also compete with public transportation but also facilitate peak shedding, alleviating peak public transit congestion.

Other studies have modeled the impacts of replacing “all” car and bus trips with a portion of trips served by SAVs that incorporate pooled rides. One study of Lisbon, Portugal forecasts when existing trips are served by a combination of SAV taxis and shuttle buses, emissions are reduced by one-third and 95% less public parking is required. Furthermore, the vehicle fleet would only need to be 3% the size of today’s light-duty vehicle and bus fleets. The study also predicts total VKT would be 37% lower than the present day during peak periods, although each vehicle would travel 10 times the total distance of current vehicles (OECD/ITF, 2016). However, SAVs could also contribute to induced travel demand due to reduced travel times and costs. More research is needed to better understand the potential of SAV induced travel demand on mode split and VMT/VKT.

Some studies have also concluded that a fleet of shared automated electric vehicles with “right sizing” of vehicles by trip, in combination with a 2030 low-carbon electricity grid, could reduce per-mile GHG emissions by a range of 63% to 82% compared to a privately owned, hybrid vehicle in 2030. The per-mile GHG reductions are 87% to 94% lower than a privately owned, gasoline-powered vehicle in 2014. Half of these emission savings are attributed to smaller right-sized vehicles based on trip needs (Greenblatt

and Saxena, 2015). However, more research may be needed to understand the impacts of SAV right-sizing on traveler waiting times as well as deadheading, particularly in lower-density built environments.

If automated vehicles (AVs) become mainstream, SAVs may constitute a sizeable portion of trips. However, travel behavior estimates are unknown. The number of personally owned AVs will likely determine, to some degree, SAV service demand. Impacts will also depend on sharing levels (concurrent or sequential) and the future modal split among public transit, shared AV fleets, and shared (or pooled) rides. It is possible that SAV fleets could become widely used without very many shared or pooled rides, and single-occupant vehicles will continue to dominate the majority of vehicle trips (e.g., users could access a shared fleet without sharing a ride). It is also feasible that shared rides could become more common, if automation makes route deviation more efficient, more cost effective, and more convenient. To date, most studies have not been able to deeply assess the propensity for pooled rides, since SAV travel behavior data currently do not exist. Travel behavior, business models, and public policy will be key components in determining how pooling and SAV impacts unfold.

Relationship Between SAVs and Public Transportation

In the future, automation could be the most transformative trend to impact public transportation since the automobile. Automation will likely result in fundamental changes to public transportation by altering the built environment, costs, commute patterns, and modal choice (Shaheen and Cohen, 2018). SAVs have the potential to create new opportunities to right-size public transit fleets and for public agencies to partner with the private sector. Reduced vehicle ownership due to SAVs could reduce parking demand and create new opportunities for infill development and increased densities. While SAVs may compete with public transit ridership, infill development could also create higher densities to support additional public transit ridership and allow for the conversion of bus transit to rail transit in urban cores. However, reduced commute stress from vehicle automation could make longer commutes more practical, reinforcing historic patterns of suburban and exurban residential choices. In the future, if more households telecommute due to an increase in flexible work schedules (at least part-time) and part-time commutes become less expensive and more productive due to AVs, today's travel time of commuting (and congestion) could be notably reduced. This could reinforce historical patterns of low-density development and private-vehicle ownership (including AVs). Additionally, SAVs could reduce public transit use, encourage lower vehicle occupancies (compared to fixed-route transit), and increase SAV trips. Just as AVs have the potential to reduce driving costs, automated transit vehicles have the opportunity to reduce operating costs and potentially pass on these savings to riders in the form of lower fares, more routes, first- and last-mile connectivity, and increased service frequency. This could make public transit more convenient and competitive with other modes, resulting in increased ridership (Shaheen and Cohen, 2018). It is important to consider this range of possible scenarios in planning for an automated vehicle future.

Summary

Studies on TNC impacts are emerging and have been shown to demonstrate varied impacts on VMT/VKT, GHGs, modal choice, automobile ownership and use, and public transit ridership, which are affected by local characteristics such as: urban density, land use, the built environment, public transit accessibility, public policy, and other factors. Many companies are beginning to explore evolving TNCs into SAV fleets. While SAV impacts remain uncertain, a number of studies suggest greater efficiency and affordability with lower GHG emissions. SAVs have the potential to impact public transportation in a variety of ways that present new opportunities for competition and complementarity. Vehicle automation could result in higher average vehicle occupancies (due to growth in shared fleets), lower vehicle occupancies (from the growth of zero occupant vehicles), or both—depending on the use case and spatial-temporal effects. While vehicle automation could transform public transportation services, leading to more cost effective and efficient service, automation could also compete with public transit, shifting riders to lower occupant modes. Policymakers should consider addressing the range of risks and opportunities associated with shared and automated mobility in planning for the future of urban mobility, including the transition to a more automated world.

Acknowledgment

The authors would like to thank the American Planning Association, the California Department of Transportation (Caltrans), the Mineta Transportation Institute, the US Department of Transportation, the Natural Resources Defense Council, and the Hewlett Foundation for their generous support of this work. Special thanks to the shared mobility operators, industry experts, and policymakers, who make this research possible. The contents of the chapter reflect the views of the authors and do not necessarily indicate sponsor acceptance.

Biographies

Susan Shaheen is a professor in the Department of Civil and Environmental Engineering at the University of California (UC), Berkeley. She is also Codirector of the Transportation Sustainability Research Center (TSRC) at the Institute of Transportation

Studies, Berkeley. She was among the first to observe, research, and write about the changing dynamics in shared mobility and the likely scenarios through which AVs will gain prominence. She was the policy and behavioral research program leader at California Partners for Advanced Transit and Highways, a Special Assistant to the Director's Office of the California Department of Transportation, and the first Honda Distinguished Scholar in Transportation at the Institute of Transportation Studies at UC Davis, where she served as the endowed chair from 2000 to 2012. She has authored numerous journal articles, reports and proceedings, book chapters, and coedited two books. She has a PhD from UC Davis and a MS from the University of Rochester.

Adam Cohen is a shared mobility researcher at TSRC at UC Berkeley. Since joining the group in 2004, his research has focused on shared mobility, mobility on demand, mobility as a service, urban air mobility, smart cities, and other innovative and emerging transportation technologies. He has coauthored numerous articles and reports on shared mobility in peer-reviewed journals and conference proceedings. His academic background is in city and regional planning and international affairs.

Introduction

This chapter considers the challenges and solutions for public transport (PT) in low population density areas, such as rural regions and outer suburbs, from economic perspective. For defining low-density areas, we use OECD's definition for rural areas, which is 150 inhabitants per km² (Dijkstra and Poelman, 2014). In these areas travel demand (per square kilometer) for PT is typically much lower than in densely populated urban areas for two interdependent reasons: (1) Total travel demand is lower, and (2) Market share of PT is lower, because private car is relative more competitive on the rural areas where bus frequency is typically much lower. The lower demand density causes economic challenges for providing PT due to relatively low revenues and cost recovery compared to PT provision in urban areas. The on-going global urbanization makes this challenge even more topical and difficult for rural areas, which sets decision makers to choose between lower service level (e.g., lower bus frequencies) or higher trip fares to maintain cost recovery. The third option is to raise subsidies instead of fares, which would require increasing taxes and plausible arguments for having political acceptance. For bringing clarity to these decisions and their mutual interdependencies, we consider an optimal PT provision and pricing in section "Service provision, pricing, and subsidies", which provide basis for the economic arguments for subsidization of PT, that is, economies of scale and underpricing of private car use (Fig. 1).

In addition, there are other political arguments for subsidies, such as equity and right to accessibility, for citizens. These various arguments for subsidies either intensify or diminish when demand density decrease. Moreover, there are certain specific arguments for organizing and supporting PT in rural areas, which are related to the wider benefits for economic activity in rural areas. For instance, PT can improve mobility of workers and job seekers, which consequently increase labor supply and thereby can support local industry and stimulate social and economic activity. These wider economic benefits are considered in section "CBA and wider economic benefits of public transport in rural areas".

The set of used transport modes and related infrastructures is the other crucial aspect of decision-making in PT provision. Traditionally, the most common PT modes in low-density areas are buses and paratransit services. Technological advancements in Information and Communication Technology (ICT) and intelligent transport technologies have increased interest for new flexible transport services (FTSs) such as automated demand responsive transport (DRT) and shared taxis. This development has already realized on the emergence of the new pilots and in some cases established FTSs, some of which operate in low-density areas. Moreover, autonomous vehicle technologies can be seen as a promising solution for cost pressures of rural PT as currently salary costs of bus drivers incur even 70% of operational costs. However, the potential societal impacts of new flexible services are multidirectional, and much is depending on how these services are implemented and priced. For instance, an increased flexibility of route typically increases driven vehicle kilometers compared to conventional fixed route services where walking distances to the bus stops are usually longer. On the other hand, flexible DRT services are driven only when needed and only to the requested pick-up locations using shortest routes whereas fixed route bus services follow predefined schedules and routes even if there are no passengers on the route (or more likely on the part of the route) for a certain hour. The decisions on transport modes and possibilities of new technologies are considered in section "Decisions on provided transport modes and the role of new technologies". Finally, last section " " presents conclusions and policy implications.

Service Provision, Pricing, and Subsidies

Decisions on provision of PT are typically done by regional or municipal transport authorities (sometimes transport operators have also significant decision-making power). However, these local transport authorities rarely (or barely ever) have a full autonomy as state legislations set boundaries on their decision-making. Moreover, government’s transport policies and investments on transport infrastructure (e.g., road and rail network) define largely the environment where the local transport authors aim to fulfil their duties. Furthermore, there are various other factors influencing on requirements and decisions of local transport authorities, such as passenger needs and demand for PT, market structure of transport service companies, citizens’ opinions, and values that influence through municipal politics. In this section, we aim to clarify these complex decisions by explaining the main results of the transport economics, which define optimal PT provision and pricing from the economic viewpoint.

The general objective for social planner (i.e., transport authority deciding on PT provision) is to maximize social welfare defined as total benefits minus costs, where the benefits are measured as total willingness to pay for using PT and the costs include the production costs of transport operator, travel time costs of passengers and external costs for society (such as pollution, noise, and congestion). With this general objective in mind, we first focus on a single bus route, which requires three main decisions: (1) A bus fleet size, (2) A bus frequency on the route, and (3) A bus ticket price. Optimal price is equal to social marginal costs, that is, incremental costs for society due to an additional passenger, which gives correct incentives for travelers’ choices, and thereby leads to an efficient allocation of resources and a social welfare maximization (Small et al., 2007; Kaddoura et al., 2015). Provision of certain bus frequency requires both buses (capital) and drivers (labor). Some essential results related to this optimization problem was provided by Herbert Mohring, who analyzed bus transportation and included also the value of travel time (i.e., travel time is an input provided by passengers) to the total costs (Mohring, 1972). He showed that to minimize costs of service provision require using that amount of capital which generate equal short run marginal costs and long run marginal costs (i.e., in the short run amount of capital is fixed). Moreover, if the long run marginal costs are decreasing in scale (i.e., decreasing with higher levels of trip supply and demand), then long run average costs are higher than the long run marginal costs, which means together with the marginal cost pricing that a subsidy (equal to the quantity of supply multiplied by the difference between average and marginal cost) is required to cover the total costs. More specifically, in bus services the main reason for the gap between average and marginal cost is that passengers’ waiting time costs decrease when bus frequency increase.

In general, the positive scale economies of PT causes that average cost of producing trips by PT are lower in urban areas where demand density is higher. Therefore, it is necessary to consider different variants of scale economies for deeper understanding economic challenges of PT provision in low-density areas. Mohring’s analysis explained so called *demand side scale economies* (decreasing waiting time costs), which is one of the main arguments for subsidizing PT. There can be also *supply side scale economies* in PT due to fixed capital costs or investments on required infrastructure (bus stops, terminals, rails, parking places or bus garages for the fleet, etc.), which are more efficiently utilized with higher scale of service provision. In addition, there are positive supply side scale economies in taxi and DRT services (which are often provided as an integral part of municipal PT), due to the shorter pickup routes of the vehicles when both the number of passengers and vehicles are simultaneously increased (and spread evenly) on geographically fixed service areas (Jokinen, 2016a).

Thus, both the supply side and demand side scale economies need to be taken into account when defining optimal PT provision and pricing. The other relevant classification of scale economies is the distinction between economies of *density* and *size*. Where the former is a form of economies of scale within a transport network when both the demand and supply of transport services are increasing and leading to lower average costs of passenger trips (as already described in the Mohring’s analysis), whereas the latter in related to (possible) scale economies of transport network extension, for example, lengthening existing bus route or adding new bus route. On the rural areas, there can be positive economies of size if, for instance, the bus route is extended for connecting two rural

villages and leading to significant increase of passenger demand with relatively small increase in costs of bus operations. On the contrary, there would be negative economies of size, if the bus route was extended to any distant location with low-demand density along the new part of the route.

In rural areas, low passenger demand and scarce resources for PT has often forced to produce other services with the same resources. For instance, bus services can also deliver mail and packets along the routes in many European and African countries, which has (at least to some extent) helped transport authors to fulfill their duties (Adams, 1981). The other example is companies that provide minibuses simultaneously for municipal school trips and for private taxi trips. In general, there are positive *economies of scope* if it is cheaper to produce several products or services in the same company than in the separate companies. In the rural areas, there can be positive economies of scope in combined provision of PT and post services (or other delivery services), because bus stops and delivery points can be combined, and these are not too densely located along the routes. Therefore, production of post or delivery service does not cause too much additional travel time costs for the bus passengers, whereas in the high-density areas these additional travel time costs would probably become too high, and consequently, leading to negative economies of scope. New technologies and digital services provide more possibilities for combined production of PT and other services in rural areas, which are considered in section "Decisions on provided transport modes and the role of new technologies."

Up to this point, we have considered optimal PT provision, pricing and subsidies without any constraints in decision-making, that is, we have considered so called *first best policies*. However, in reality decision-making is limited by many constraints related to legislation, political acceptability or budget constraints. Optimal decisions under these type of constraints are called as *second best policies*. One common such constraint is related to pricing of private car usage, and more specifically, to an incapability for adjusting prices dynamically with congestion levels. Marginal social costs of private car usage are high during congested peak hours leading to underpricing of private car due to the lack of congestion pricing scheme. Thus, in this case the welfare maximizing principle of marginal social cost pricing is violated, which causes a constraint for defining (second best) optimal PT provision and pricing. Now, if there is a positive cross elasticity between PT and private car, that is, price decrease of PT attracts private car users to shift their transport mode to PT (and vice versa), then it is optimal to subsidize PT for reducing congestion costs. This is so-called second-best argument for subsidizing PT. On rural areas congestion is a relevant challenge mainly only on highways, but it can have, however, a crucial effect of travel time costs of commuters, and consequently on local labor supply and economic activity of rural areas, especially, if a significant share of rural population commutes long distances to workplaces. Moreover, mode choices of rural commuters can have influence on the congestion of the nearest urban areas. This interaction between low- and high-density areas should be taken into account in the transport policies of larger areas (e.g., states or provinces), and it gives one argument for government subsidies for rural public transportation.

CBA and Wider Economic Benefits of Public Transport in Rural Areas

Thus far, we have considered the optimal policies of PT in low-density areas. The presented results provide understanding of economic arguments for subsidies and other related policies. However, the decisions on PT provision can be evaluated also, regardless of optimality conditions that are often (somewhat) ignored in political processes, by a more general appraisal method of cost–benefit analysis (CBA), where a proposed transport investment or policy change is evaluated by estimating expected future benefits and costs for users and society. The CBA gives an evaluation whether the benefits outweigh the costs, that is, is a certain policy or project economically reasonable. Moreover, the CBA can be used to rank alternative policies and projects in a decision-making situations where only one or some of the all proposed projects can be implemented (Börjesson et al., 2014). The CBA has been used widely for evaluating PT in rural areas. Godavarthy et al. (2014) provide a review of implemented cost–benefit analyses on rural PT in the United States. They mention three relevant areas of benefits of rural PT: (1) Transportation cost savings including internal costs like travel time costs and chauffeuring costs (e.g., parents cost for driving children to school and hobbies) and external costs such as car emission costs and traffic accident costs (which are only partially internalized); (2) Low-cost mobility benefits, which are realized from trips that would have been foregone without rural PT like medical and educational trips of noncar population; (3) Economic benefits that relates to economic activity induced by rural PT.

In general, the conventional CBA focuses on evaluating and comparing user benefits and costs. However, there can be also other substantial wider economic effects induced by transport projects. Vickerman (2008) identified four wider effects of large transport projects: (1) productivity effects, (2) agglomeration effects, (3) competition effects, and (4) labor-market effects.

The productivity effect relates to the results that infrastructure investments have positive effect on economic output especially on regions where the lack of infrastructure has constrained local economy to integrate into wider markets. For instance, rural PT can benefit local tourist businesses by making their services available for new customer segments.

The second wider effect, that is, agglomeration effect, is usually referred to the benefits from proximity of similar companies in urban areas (e.g., cooperation in R&D and larger labor pool in the area). However, the proximity can be seen as a relative concept, and therefore, even in rural areas improvements in transport services can bring companies closer and similarly advance mutual cooperation between companies.

The third effect (on competition) was first identified by Jara-Diaz (1986), and relates to the effect that transport investment can reduce market power of local monopolies and thereby reducing deadweight, and thus create positive external effect (i.e., increased competition forces companies to produce more with lower prices). The market power of local monopolies can be high in isolated rural areas. However, these type of isolated markets are likely rare in the most developed market economies (Vickerman, 2008).

Transport investments can have effects on labor-markets if travel costs of commuters decrease and companies have access to a larger labor supply, which decrease wages due to competition, and provide more skilled and productive labor. Thus, investments on rural PT can have effects on the labor-markets both on that rural area and on the nearest urban centers, because improved PT connections attract rural population to work in the nearest urban areas, and, respectively, employers in the rural area can attract skilled labor from the urban area.

In addition to these four wider benefits influencing on other markets (i.e., beyond transport markets), rural PT have other benefits for citizens that are also so called wider benefits (or values) in the sense that these are not directly related to the use of PT, that is, option values and nonuse values. Option values are based on the value of the possibility to use PT either in unusual situations when, for instance, own car is not available or in the future when changes in life cause a need for PT. For instance, rural train can become attractive transport mode due to finding a new job. In contrast to option values, nonuse values are unrelated to the use of PT, neither occasionally now nor in the future (Johnson et al., 2013). Nonuse values of rural PT can be related to altruistic values (e.g., valuing equal accessibility and social inclusion for the all citizens) and indirect user benefits. However, Johnson et al. (2013) note about scope for significant overlap between nonuse values and user benefits or externalities that are usually taken into account in the conventional CBA.

Decisions on Provided Transport Modes and the Role of New Technologies

The Role of New Transport Modes and Technologies

PT is undergoing disruptive changes mainly induced by developments in the ICT sector. After decades of political prioritizations of motorized individual transport (Wallin Andreassen, 1995), a societal and political shift toward new mobility concepts induced by demographic change, austerity policies, environmental, and climate concerns is occurring. New mobility services address the heterogeneous consumer preferences which traditional PT services could not satisfy. Thus, a change on the demand side for mobility has developed over the past years. A simultaneous shift in the car and services industry results in new providers of shared mobility services, a traditionally publicly dominated sector (or dominated by informal sector in many developing countries). The supply side of the mobility market is, therefore, also changing with so-called mobility as a service (MaaS) concepts (Aapaoja et al., 2017). Most of these new modes address the shortcomings of the traditional PT services, for example lack of flexibility and supply in rural areas. Based on the potential to reduce car dependency and car usage for people in rural areas, innovative PT can play an essential role in a modal shift or at least alleviate the economic challenges of rural PT caused by urbanization and diminishing rural population. For the rural areas, however, with lower population-densities the developments differ significantly to those of urban areas where manifold new transport modes are made available, for example, e-scooter or car-sharing services. Many transport modes are unfeasible due to a lack of economies of scale, for example, because of the small numbers of passengers a metro or tram line is inefficient in low population areas. Consequently, mainly busses, rail services and some taxi services exist in these areas. Hence, the share of PT for overall mobility is still low (Pucher and Renne, 2005). Over the past decades, however, the fixed schedule and fixed route services, for example, buses and light rail services, were complemented or substituted by more flexible and DRT (Mounce et al., 2018). While the former conventional modes are heavily regulated the latter new modes are only slowly falling under regulations. These circumstances are result as well as reason for new mobility providers in the markets, especially in urban areas, who benefit from an unregulated and innovative environment. However, new transport modes in rural areas are sparse since innovation requires time and political support to disperse toward less populated regions. Under these premises, innovative mobility services may help to reverse the low public transportation supply and demand in rural areas. For many innovations in the transportation sector, certain ICT requirements exist, which are commonly fulfilled in developed countries. In developing countries, however, the situation may differ and innovation is less dispersed, such that many of the new transport modes and technologies described here are not yet feasible in all areas worldwide.

Demand Responsive Transport

A prominent example for innovation in rural PT is DRT services. These DRT services are a technological evolution to former dial-a-ride services which were available in the 1970s (Guenther, 1970; Gustafson and Navin, 1973; Li and Quadrioglio, 2010; Roos et al., 1971). Many of formerly purpose-oriented DRT services are now being merged into services addressing the broader rural population with the goal of an efficient use of resources, for example, vehicle seats or bus drivers. DRT services are commonly positioned between regular bus and taxi services. As an example, Wang et al. (2015) describe DRT services as follows: (1) The service is publicly available, (2) it applies small busses or vans, (3) depending on demand the route and time is dynamically adapted, and (4) the fare is to be paid per passenger as it is in conventional public busses.

DRT concepts are also referred to as FTSs (Velaga et al., 2012). These FTS or DRT services can follow different structures and setups: For one, the scope of route flexibility can vary, for example it can follow specific virtual stops or is limited to pick-ups and drop-offs along in certain areas or it can come as a true door-to-door (also sometimes called curb-to-curb) service. For two, there can be time constraints on prebooking times. Some FTS allow bookings with a prebooking time of several days while other services may be limited to prebooking times of 1 h or even only instant trips. The specific technical infrastructure is mainly dependent on the envisaged form set by the operators and local transport authorities. Research on ideal setups for specific circumstances exists and indicates that certain characteristics of an operation area require consideration in the respective service setup (Velaga et al., 2012).

In combination with the terms of DRT and FTS the concepts of *ride-sharing*, *ride-pooling*, *ride-sourcing*, and *ride-hailing* are frequently mentioned (Machado et al., 2018). These concepts, which are often used interchangeably, differ significantly regarding several dimensions, for example, the supplying entity or technical setup. However, similarities exist as most concepts have comparable goals, for example, reduction of travel costs per person, or an improved environmental impact due to lower emissions compared to individual rides.

Ride-sharing generally refers to combining commutated trips in one vehicle. In comparison to *ride-pooling*, it is privately organized and also privately operated, for example, employees of the same company share a car for their commute. Hence, the driver and passenger(s) share an identical or similar destination. It has been argued that ride-sharing is motivated by other reasons than profit (Chan and Shaheen, 2012). Related terms are car-pooling, car-sharing and lift-sharing. *Ride-sourcing* can be used synonymously with ride-sharing (Jin et al., 2018). Ride-sharing initiatives often relate to periods of scarce resources and lower welfare, for example, during the World War II. Ferguson (1997) links the reduction in carpooling for the United States between 1970 and 1990 to the increased number of vehicles per household and lower costs, for example, fuel costs.

Ride-pooling requires an organizing entity that matches commutated trips. This organizing entity is nowadays an ICT system including vehicle dispatching algorithm and routing algorithm that utilize real-time location and trip request data that assigns similar trip-requests to a specific vehicle along a dynamic route. The concept of ride-pooling combines characteristics of ride-sharing and ride-hailing if, for example, a transport authority offers an on-demand mobility service where passengers demand (hail) a vehicle to be transported to a destination by a driver. If there are no further trips pooled along the route, the offered service to the customer shows all characteristics of ride-hailing aside from being publicly accessible during and along the route.

Ride-hailing refers to the traditional hailing of a taxi for transportation. In general, it refers to the traditional means of requesting transportation as an individual trip through a virtual path, that is, mobile applications. In that, it differs from the ride-pooling concept as only one trip at a time is serviced and ride-hailing does not fall under the concept of sharing a trip (see Frenken and Schor, 2019). In an analysis of vehicle miles travelled, Henao and Marshall (2019) found two prominent ride-hailing services, Uber and Lyft, to increase vehicle kilometers driven compared to the number without ride-hailing services. Their investigation is centered around the US city of Denver implying that for rural regions ride-hailing services might further increase the vehicle kilometers due to longer deadheading.

Concerning the question of the supplier of mobility services in rural areas, either public or private entities can provide ride-pooling or ride-sharing. However, considering the relatively high subsidy requirement of transportation in low-population density areas due to higher costs compared to possible revenues, public entities are likely to remain responsible for mobility provision. For example, Soder and Peer (2018) state that mobility provision through employers in an Austrian rural area is socially and economically inefficient.

Research on drivers of DRT usage are still as sparse as operational DRT services. Therefore, only few insights on relevant factors for DRT usage are available. Wang et al. (2015) categorize them into *service-related*, *area-related*, and *individual-related* factors. Waiting time, in-vehicle time, service frequency and overall time and route flexibility are service-related factors that influence DRT usage (see Tyrinopoulos and Antoniou, 2008; Takeuchi et al., 2003).

Benefits and Challenges

For a transport mode to be used by many customers, the benefits must outweigh the costs especially compared to individual transportation modes, for example, the car. Thus, flexibility and availability are commonly mentioned in this context. DRT meets these challenges and is intended to supply a flexible and financially viable transport service. At the same time, DRT services may allow to combine different transportation services by incorporating services with a specific user group, for example, trips for medical examinations. Overall, societal gains can result if the new transport modes are implemented under consideration of regional circumstances. By reducing social exclusion based on the lack of mobility it can further help to revitalize rural areas (Farrington and Farrington, 2005). Fransen et al. (2015) show that lack of mobility contributes to social disadvantages. López-Iglesias et al. (2018) highlight the potential for rural development by connecting rural hinterlands with local functional areas. Also, Hough and Taleqani (2018) conclude that technological developments are likely to revive rural areas because of higher livability and accessibility through innovative transport modes. For the long-run, analyses of the induced travel effect, that is, the creation of further travel demand by an extended mobility supply, will be of interest (Rayle et al., 2016).

In case a DRT service manages to substitute private individual car usage, environmental benefits are a direct and indirect result. A direct effect can be achieved through less vehicle emissions when ride-pooling is realized through DRT. Indirect effects relate to less traffic and, thus, less congestion, less additional cruising in search for parking and freed up parking spaces. For rural areas, the lack of parking spaces is unintuitive, provided that space is abundant and, thus, pricing of land is lower compared to densely populated areas. However, topographical circumstances can limit available space, for example, for parking, even in rural areas. For example, in a rural tourism context, the DRT service *EcoBus* in central Germany helped accessibility of mountainous skiing areas during snow periods while some streets were blocked due to the lack of parking in the Harz region. However, as Le-Klähn and Hall (2015) state, PT still only play a minor role in tourism for remote or rural areas. Thus, innovative approaches to PT such as automated DRT may help to attract tourists for rural regions. The importance of PT for sustainable rural tourism has been highlighted by Tomej and Liburd (2019).

A challenge in new mobility services is the consolidation of several services, for example, taxi services. As DRT can be positioned between regular bus transport and taxi services, the latter may be pushed out of the market. However, for specific tasks a ride-pooling

service may still be too inefficient or inadequate such that regular taxi services could account for that niche market. Eventually, some providers could shift or be included in a public DRT service while some remain to meet the excess demand. In this context, it has to be mentioned that diversity in transport services may enhance the overall PT provision and should be a desirable situation in the long run. Therefore, transport authorities are required to increase cooperation to provide integrated services to their passengers. Intuitively, new rural PT solutions should alleviate the segmentation among providers to allow for an integrated and broad service (Hough and Taleqani, 2018). However, funding (especially subsidy) structures need to adopt accordingly. Again, cooperation among providers is key for the future of innovative PT provision.

Outlook

In the future, autonomous driving will induce the development of new services in the public transportation sector. Commercial shared autonomous vehicles (SAVs) could replace PT in areas where mass transit is economically inefficient (von Mörner, 2019). Thus, SAVs inhibit high potential for rural and low-density areas where mass transportation is unviable (Herminghaus, 2019). For regular PT services and more importantly for DRT the cost of personnel often prevents a broad application of innovative services. For developed countries, the lack of drivers imposes an operational constraint and can limit the quality of service for customers. Therefore, SAVs can help to meet the shortage in labor supply and, in addition, reduce the operational costs for the service providers, for example, the transport authorities. As Litman (2009) points out, lower transportation costs per capita are achievable through ride-sharing compared to any other motorized transport. In reference to societal costs of transportation, Jokinen (2016b) identifies DRT services to inhibit lower societal costs compared to private car and taxi if demand is sufficient. Under the assumption that new mobility services attract more users and relieve the car dependency, Stiglic et al. (2018) highlight the high potential in cost efficiency for PT with integrated intermodal services.

However, in most rural areas the ICT infrastructure will pose a bottleneck for a broad adoption of autonomous vehicles (König and Neumayr, 2017). In reference to the application of technology in new mobility concepts in rural areas, the standards, practices of public-private partnerships and more importantly the respective laws and regulations need adjustments in the process (see Hensher, 2017).

Conclusion

In this chapter we have presented some essential results of the economics of PT, which define welfare optimal provision and pricing of PT under general market conditions and give economic arguments for subsidies, that is, economies of scale and underpricing of private car. Thus, the presented results explain why subsidized public transport is needed as a crucial part of efficient and sustainable transport systems. These general results are relevant also for low-density areas, but certain specific characteristics, such as lower total demand for transport and more scarce resources available for PT provision, must be taken into account in optimal policies. In addition to these results and economic arguments, we have considered the use of the CBA in evaluation of rural PT projects, and reviewed some potential wider economic benefits, which are relevant also in rural areas but can take different forms than in urban centers. The ongoing urbanization causes more cost pressures for maintaining rural PT. On the contrary, at the same time environmental concerns drive society to develop and provide other transport modes than private car. From these economic and societal viewpoints, we have considered the role of new technologies for maintaining and even improving rural PT.

As rural demographics show a negative trend for developed countries, mobility services will be necessary in the context of social inclusion through mobility or access to medical services for immobile people. Thus, it has to be recognized that PT will be a vital aspect for rural communities in the future and requires adjustments accordingly. In this context, the financial burden should be reflected upon overall societal costs and benefits, for example, the provision of innovative PT in rural regions may be costly from a community perspective but under consideration of the private costs, that is, through individual motorized transport, the environmental, congestion, and other costs are relevant for an overall evaluation. Therefore, introducing new innovative transport services in rural areas may allow for societal benefits and cost savings if applied strategically and efficiently. Close cooperation between a supervising transport authority and local stakeholders is essential in assuring that services are compliant with the demand in certain areas.

Several policy implications arise from the presented results and recent developments in PT services. One implication is that conventional bus services with fixed routes and schedules are not economically reasonable in the most depopulated areas, where travel demand for PT is too low and irregular, which can be verified by the CBA. In practice, this has led transport authorities to replace conventional PT by more FTs in many rural areas in order to ensure sufficient accessibility of citizens with lower costs. Apart from these most depopulated areas, there is need also for conventional rural PT which provides together with FTs significant benefits for users and usually enable wider economic benefits for rural areas and even for surrounding urban centers. An important aspect for the rural regions is cooperation between transport providers to realize economies of scale. For instance, the schedules of bus services and operating times of DRT should enable comfortable transfers to the rural train. The usage of integrated, multimodal smart services can only be fruitful if it is not limited by regional borders or insufficient cooperation between transport operators. The presented results and methods can improve mutual understanding of the potential benefits of rural PT and new technologies for the whole society, and thereby enhance cooperation between transport authorities, companies, politicians, and citizens.

Introduction

Government is heavily involved in the transportation sector, both in the infrastructure and services provision and management. The transportation industry is characterized by several market failures, that is, situations in which the free market does not ensure an efficient outcome. Two types of market failures are particularly noteworthy: the cost structure, which exhibits declining average costs leading to natural monopoly, and the presence of several externalities.

As far as the cost structure is concerned, in most of the segments of the transport sector, a large portion of the total costs is fixed, which gives rise to economies of scale. Under these circumstances, monopoly is the most cost-efficient market structure (de Palma and Monardo, 2021). This cost structure is typical of infrastructures, including highways, railways, airports, ports. However, it is shared by many other transportation services as well, including, most prominently, public transit (Parry and Small, 2009).

Several externalities are involved in the transport sector. Two of them, particularly relevant, have to do with pollution and congestion. The transport sector is one of the greatest pollutants. In Europe, transport represents almost a quarter of Europe's greenhouse gas emissions and is the main cause of air pollution in cities. Within this sector, road transport is by far the biggest emitter accounting for more than 70% of all GHG emissions from transport in 2014, according to data from the European Energy Agency. ADD FOOTNOTE(See https://ec.europa.eu/clima/policies/transport_en.) In the United States, 29% of the greenhouse gas emissions in 2017 comes from transport (EPA, 2020).

Congestion is a negative externality that is typical of the transport sector. An increase in the utilization of an infrastructure negatively affects all the other users of that infrastructure. If the external effect is not appropriately priced or regulated, this can result in an excess congestion, above the socially optimal level (Franco, 2021).

The nature of the policies that governments can and do use depends on the source of the distortion they target. However, the different forms of government intervention to correct all these distortions may be classified on a spectrum ranging from *direct* government intervention, which directly impose a choice or a behavior to firms or to consumers, to *indirect* interventions aimed at modifying the incentives of the suppliers or of the consumers, so as to indirectly trigger a change in their decisions.

When government intervenes to mitigate market power, a straightforward form of *direct* government intervention consists in public ownership. This approach is based on the presumption that government-owned firms may efficiently operate with the objective of pursuing the welfare of the society as a whole. *Indirect* intervention, instead, involves delegation of the strategic choice to the firms, while setting up an appropriate incentive scheme, in the attempt to align their behavior to social optimality. This takes the form of incentive regulation. The most relevant example of this approach is provided by the price cap regulation for monopolistic firms, used, for instance, in the highways sector in some European countries. Under price cap, the price choice is delegated to the firm, under a set of constraints on their (average) level, which is meant to prevent the firm from exploiting its market power. A large array of instruments lies in between (and sometimes intersects with) these two forms of intervention, including rate-of-return regulation, procurement auctions, and concessions.

Finally, government intervention aimed at mitigating environmental or congestion externalities can also be broadly classified either as *direct* or *indirect* intervention. A *direct* type of intervention is for instance command-and-control regulation, which directly imposes a choice or a behavior to market participants; in other words, it directly intervenes on what market participants can and cannot do. On the other hand, *indirect* forms of government intervention are all those market-based regulation under which the government attenuates inefficiencies, for instance, by imposing an extra cost (such as a price or a tax) on those generating the externality, so as to modify their incentives, and to align their behavior to social efficiency.

Both command and control (C&C), and market-based regulation can be applied both to firms and to users. When directed to a firm, C&C may involve, for instance, setting an emission standard for pollutants in the energy sector and fuel economy standards in the automotive industry. When directed to consumers, C&C involves setting outright obligations, or, more frequently, prohibitions. Examples include precluding access to city centers to more polluting cars, or making a zone pedestrians-only. Market-based regulation applied to firms may involve, for instance, the emissions trading systems, which imposes an extra cost on the activity

of polluting firm, in an attempt to induce either less production (and thus pollution) or the adoption of cleaner technologies. When applied to users, they may involve congestion charge to disincentivize the use of congested infrastructures.

In this chapter, first start by considering government intervention related to market power. We then move to considering environmental and congestion externalities. We will keep an eye on how recent and prospective technological evolutions, in particular in terms of transition to electric and autonomous vehicles, have affected or have the potential to affect the scope and the structure of government intervention.

We argue that indirect policies are in general superior to direct policies in addressing externalities, while, when government intervention is geared at reducing market power, the relative performance of direct and indirect intervention is less clear cut and strongly depends on the institutional environment.

Market Power

Market power in the transport sector arises in almost the entire range of transportation modes since they displays scale economies, under which the unit average cost decreases as output increases.^a Typically, scale economies derive from the existence of large fixed cost, which are indeed prevalent in most transport industries. Prominent examples include highways, airport, ports. In industries where scale economies exist, there are limits to competition, in the sense that profitable operation is possible for a limited number of firms only (de Palma and Monardo, 2021).

It is well known that, in industries with such inherent limits to competition, the traditional perfectly competitive prices not only do not occur when the firm(s) operating in the market are left free to operate, but would also be impossible to apply by a social welfare maximizing entity, absent subsidies. If all costs need to be covered, prices equal marginal cost—the standard result of a perfectly competitive market—would be unable to cover all the firm's costs. A large body of literature has contributed to the identification of socially optimal prices in the presence of limits to competitions. These prices go under the heading of Ramsey prices and, in their simplest version, imply that, for each good, the departure from marginal cost pricing is larger the less elastic is the demand for that good (De Borger, 2021, ET; Guo, 2021). This pricing rule reflects the intuition that relatively higher prices are set for goods with relatively lower demand elasticity, since the little reduction in demand results in few foregone (but welfare-enhancing) trade opportunities.

The main issue to be tackled by a policy maker is then how to implement these optimal prices. The traditional solution is public provision, either by a governmental department or by a state-owned firm. Highways, railroads, ports, and airports are frequently publicly owned or publicly provided around the world.

Direct government ownership, however, is no guarantee of welfare-maximizing behavior, because of at least two types of distortions. First, principal-agent distortions. Even when the government directly manages the infrastructures, it must rely on a governmental operational department, composed of managers and of employees who are likely to have private information on the costs and benefits of the activities, and an objective function not fully in line with welfare maximization, but instead related to their private benefits. Second, political economy distortions. The government does not necessarily maximize welfare. Politicians might not respond to citizens' needs, especially when they feel their behavior is not adequately observed and scrutinized by the public (see Besley and Burgess, 2002, Strömberg, 2004, and Boffa et al., 2016).

An alternative approach to limit the distortions caused by market power is to leave the production activity in the hands of private firms and to regulate them. Economic regulation implies a much greater reliance on market forces, which may however vary across the different instruments used. It basically consists in the set of rules that (1) defines the market structure of the industry and (2) constrains the behavior of firm(s) operating in the industry.

In many industries, technological advancements have created the possibility of breaking up the vertical structure of the industry, separating the different stages of the supply chain. A typical example in the transport sector is the railway industry. While the operation of the railway infrastructure was previously seen as inherently connected to the provision of rail transportation services, these two segments of the industry are now considered to be separate.^b The effect of this change on the economic regulation of the industry is dramatic. While the infrastructure keeps the features of a natural monopoly, the technology of the commercial segment allows for the existence of an (imperfectly) competitive industry.

The government intervention in such situations may take different forms, which again show a different degree of reliance on market forces. The more traditional is clearly the one of preserving the vertical structure of the industry and to regulate it as fully integrated industry. By so doing, the government gives up the benefit of competition in some stages of the production process but, at the same time, allows the industry to exploit the existence of possible economies of scope, which make vertical integration more efficient. Alternatively, the government policy may be aimed at opening up to competition all those stages of production in which this is economically feasible. The main issue is then to define if and under what conditions the firm operating in the natural monopoly segment of the industry is allowed to operate also in the competitive segment(s). The solutions adopted here are very different, ranging from a full ban to subtler provisions. These may simply require legal or managerial separation (while maintaining common ownership) between the entities operating at the different stages of the vertical structure, possibly coupled with

^a More rigorously, fixed costs are associated to scale economies in the case of single-output technologies only. Conditions for the existence of scale economies for multiproduct firms are provided in Panzar (1989), which also provides conditions for the existence of a natural monopoly, based on subadditivity of costs, and for the existence of a natural oligopoly.

^b In the EU, see the so called Fourth Railway Package, comprising Regulations 2016/796, 2016/797, 2016/2337 and 2016/2338 and Directives 2016/798 and 2016/2370.

nondiscrimination constraint and (antitrust) controls, or impose some ex-ante pricing constraints on the essential input provided by the monopolist to the competitors in the competitive market.

Another possible approach to market design to correct market power distortions would involve relying on competitive forces not at the market stage but rather at the stage of selection of the firm(s) entitled to operate in the market (van de Delde and Hirshhorn, 2021). This is the case of the so-called competition “for the market,” as opposed to competition “in the market.” This approach is rather common in local transport, where the right to operate is awarded by means of a competitive tendering. The competitive awarding mechanism is supposed to ensure that production is undertaken by the most efficient firms and to extract through the franchisee fee the economic rent due to market power. In most cases, this approach is coupled with some additional forms of regulation, meant to limit this rent and prevent other distortions on strategic variables chosen by the franchisee that are of particular importance to the society.

Given the market structure, regulation then imposes a number of (ex-ante) constraints on the behavior of the firms(s) with market power. The vagueness of the term “behavior” is meant to include all aspects of a firm’s strategy, including prices, quality levels, product range, investments, customer relations, etc. For the sake of space, we will focus our discussion on price and quality regulation only.

Price Regulation Involves Two Dimensions: Level and Structure

The level of the regulated prices positively affects the firm’s profits but negatively consumer’s welfare. It is therefore the objective of price regulation that the level of prices is set to ensure profits just high enough to keep the firm in operation. The traditional solution of cost of service regulation (otherwise known as rate of return regulation), under which the price level is set to cover ex post all firm’s expenditures, is well known to suffer from great inefficiencies, often dubbed as gold-plating (Averch and Johnson, 1962). The “new economics of regulation,” having recognized these inefficiencies, has proposed the approach of incentive regulation. Under this approach, any rent left to the firm is used to incentivize it to pursue productive efficiency. In the case of optimal regulation, based on the truthful revelation of the firm’s private information on its costs, a high rent acts as a reward to efficient firms only (Laffont and Tirole, 1993). In the more applicable case of price cap regulation, the price level is set to prospectively ensure the firm’s breakeven for a limited period only (regulatory period), thus leaving to the firm any excess profit due to higher than anticipated efficiency. This excess profit is the cost for the society of giving to the regulate firm the incentive to efficiency (Littlechild, 1983).

The regulation of the price structure is probably the most prominent example of the difference between direct and indirect government intervention in the regulation of firms with market power. The traditional approach of cost of service regulation implied a close involvement of the regulator/public authority in the determination of the price structure. In practice, the price structure were jointly determined by the firm and the regulator/public authority, each pursuing its objectives. In the case of the regulator/public authority, these objectives were clearly manifolds, from efficiency to distributional, and often comprising evaluations of the external effects of the operation of the firm, from environmental to labor issues (Kahn, 1988).

Price cap regulation has represented a radical departure from this approach, in that the regulated firm only faces a set of price constraints imposed by the regulator. The main constraint caps the average of all prices, but it is often complemented by additional constraints on single prices or subsets of them. This leaves the firm free to decide independently its price structure. The delegation of the choice of the price structure to the firm illustrates an extreme example of reliance on market forces. Indeed, the basic motivation of this approach is that, in the absence of other distortions besides market power, the regulated firm is believed to have incentives aligned to those of the regulator as to the structure of prices. Intuitively, as in the case of Ramsey prices in the case of a public decision maker, the firms prefers to charge relatively higher prices for the goods whose demand is less elastic to prevent an excessive reduction in demand, which would reduce profits too much. (Bradley and Price, 1988; Vogelsang and Finsinger, 1979).

Another relevant object of behavior regulation is quality. As discussed before, firms with market power have a distinct incentive to provide an inadequate level of service quality. Also in this case, the regulatory provisions may rely on market forces in different ways (Sappington, 2005). At one extreme, zero reliance on market forces implies mandatory levels of service quality. In the case of transport, this is the approach typically used for some quality aspects in local transport service contracts, which include detailed standard of services, in some case coupled with damaged customer compensation when the standard is not met. At the other extreme, a quality index is included in the price cap level, as it happens, for instance, in the case of some highways concessionaires in Italy (Benfratello et al., 2009). As the level of quality provided by the price capped firm increases, the same firm is allowed to charge a higher average price level. This regulatory approach is based on market forces in that it is intended to mirror the mechanism, typical of competitive markets, under which a higher quality allows a firm to set higher prices (De Fraja and Iozzi, 2008).

Environmental Externalities

The contribution of the transportation sector to pollution is substantial. Total carbon dioxide emissions from road transportation exceed five gigatons annually, and the sector accounts for about 13% of global greenhouse gas emissions (Anderson and Sallee, 2016).

Mitigation can alternatively take the form of a reduction in the amount of transport, possibly by exploiting technological opportunities to increase work from home, or by a decrease in emissions per km traveled. In turn, decrease in emissions per km traveled can come through an environmentally-friendly improvement in the technology that moves vehicles, or through a more efficient use of the space on vehicles.

Given the current technological trends, the decrease in emissions per km traveled comes either from the improvement in mileage per unit of space of conventional fuels (unleaded and diesel), or from adoption of new technologies, among which the primary option appears to be the adoption of electric vehicles. It has to be emphasized that the impact on emissions of the development of electric vehicles crucially depends on the emissions in the electricity sector.

In this section, we will concentrate on the comparison between the predominant indirect and direct policies in the transport sector, respectively fuel tax and fuel standards, whereby the regulator directly sets a maximum mileage standard for each firm. In principle, emissions standards could also be tradable, thus becoming a hybrid between a direct and an indirect policy. However, in the current regulatory practice, they are generally nontradable, and we will consider these only in this review.

Fuel taxation has been ubiquitously adopted. Fuel standards have also been extensively used in the past. United States and Japan have had them for a long time now. More recently, other regions, including, notably the European Union, China and India, have joined them in the adoption. While the details in the implementation differ across countries, all the programs broadly impose to automakers a maximum average, usually weighted by sales, emissions rate (Davis and Knittel, 2019).

To compare fuel taxes and fuel standards, we follow closely Anderson and Saltee (2016), and we start with the analysis of the effects of a tax.

Cars, under a fuel tax, turn more efficient and shrink in size. This is consistent with empirical evidence in Busse et al. (2013) and Beresteanu and Li (2011), who show that a \$1 increase in fuel tax decreases average mileage per gallon by approximately 4%.

Second, consumers drive fewer miles. This is consistent with recent evidence in Gillingham and Nielsen (2019), who, using a rich dataset in Denmark, find that, on average, the elasticity of distance traveled to fuel prices is at about -0.30 (a value within the range provided by the literature that generally estimates an elasticity between -0.10 and -0.30, see Yang et al., 2020). Interestingly, the response to fuel prices comes primarily from very short or very long trips.

Third, consumers hold fewer cars, due to the increase in the costs of operating new cars, and they scrap inefficient cars earlier. In general, fuel prices are an important determinant of scrapping decisions. Jacobsen and Van Benthem (2015) estimate a -0.7 elasticity of scrapping to fuel prices.

We now move to fuel economy standards. While some of the effects of fuel standards are similar to those of a tax (for instance, cars turn more efficient and shrink in size), some other effects differ markedly. First, the standards generate the rebound effect. With more efficient cars, travelers are incentivized to travel more miles, which reduces the impact on emission reduction. Gillingham (2020), in his review, shows that the rebound effect eats up about 10% of the emissions reduction benefits from efficient cars. Second, fuel standards only reduce emissions for new cars, while a fuel tax, by affecting traveled distances, has an impact on used cars as well. Third, differently than with a tax, fuel standards do not provide incentives to own fewer cars, so that the automobile market size should not shrink, and, under some parametric specifications in Anderson and Saltee, might even increase. Fourth, relatively to a fuel tax, with a fuel standard consumers delay scrapping of inefficient old cars. Jacobsen and Van Benthem (2015) show that 13%–16% of the savings anticipated for new vehicles are offset by the delay in old vehicles scrapping.

All the above effects have been derived by considering an optimal (in a second-best sense) design of the fuel standard. In fact, most of the fuel standards implemented around the world are designed in a suboptimal way, which, as Anderson and Saltee point out, further induce to regard fuel tax as a more efficient form of regulation.

Possibly a result of all the above considerations, a survey administered to top economists (IMG, 2011), shows that 90% of them prefer a fuel tax over a fuel standard.

Congestion Externalities

One of the most relevant externalities in the transportation sector depends on congestion. The yearly congestion cost has been estimated to amount to more than one hundred billion dollars in the United States, and to be steadily increasing over time (Schrang et al., 2011).

However, congestion issues are even starker in developing and emerging economies. Based on real-time traffic data in 390 cities from 48 countries in 2016, TomTom Traffic Index shows that among the top 20 most congested cities (population over 0.8 million), all but 1 are located in developing and emerging economies with 8 of them being in China. Drivers in the most congested city spend much more time on average than they would have absent congestion, up to 66% or 227 hours per year per-capita in the extreme of Mexico City – the top city on the list. But, even if one considers Beijing, number 10 on the list, figures are still striking: 46% extra time on the road, or 179 hours per year per-capita due to congestion (Yang et al., 2020).

If not subject to an appropriate direct or indirect regulation, a driver does not fully consider the cost imposed by driving on a congested road. Part of this cost is external, since the driver also affects all the other drivers leaving after him. If not appropriately taken care of, congestion externality can severely affect welfare.

The mitigation of congestion, and of its resulting externality, may occur primarily in two ways. First, through an increase in road capacity, so as to accommodate the demand for cars, without creating congestion. Second, through a reduction in travel, either through an improvement in public transit, or through a better utilization of available capacity, for instance through car pooling. Observe that reduction in travel also achieves the goal of reducing environmental externality.

Based on evidence in Duranton and Turner (2011), increase in road capacity and increase in public transit usually do not prove effective tools at mitigating congestion. Increasing road capacity induces an increase in demand, originating from current residents, increases in commercial traffic, and migration that leaves congestion unaffected. Also, there is no evidence that provision of public

transportation affects travel, and, as a result, congestion. Having ruled out actions on the enhancement in infrastructures and in public transportation, we are left with the two alternatives of an indirect and direct policies to mitigate congestion, through a reduction of the number (or size) of vehicles on the road, or through their optimal allocation across time and space.

The standard indirect instrument to deal with congestion is road pricing. The simplest, and effective, form of road pricing is a Pigouvian tax equal to the non-internalized portion of the congestion cost, defined as *congestion charge*.

Pigouvian congestion charges achieve optimality when drivers do not factor in their decision the effects of their behavior on other drivers. Boffa et al. (2020) show that the taxation scheme to mitigate congestion will have to change as autonomous vehicles will replace conventional cars, and as fleets will gain prominence over privately owned vehicles. In the absence of policies or of market design interventions, congestion costs are indeed not bound to disappear when AVs will be deployed. However, when the mobility services will be provided by fleets of vehicles, the fleet operator will, at least partially, internalize the congestion costs (at least the portion that is imposed on travelers supplied by the same fleet), so the optimal tax will have to be tailored accordingly.

It is well-known that congestion charges, when optimally set, achieve optimality. However, while strongly advocated by economists, these are rarely implemented in practice (notable exceptions include London, Stockholm and Singapore), because of political economy reasons, given they are usually disliked by voters (Oberholzer-Gee and Weck-Hannemann, 2002).

When congestion charges cannot be implemented, it is possible to resort to direct policies, which, however, are certainly second best. An example is high occupancy vehicle lanes (HOV) policy, analyzed, among others, by Bento et al. (2013). They use 8 years of traffic flow data for 1700 locations in Los Angeles and show that the mean elasticity of flow with respect to fuel price for HOV is 0.136, which implies, for a 10% increase in fuel price, \$8.8 million per year in additional congestion costs for carpoolers and \$11.3 million lower costs for non carpool drivers. The estimates imply that, while HOV policy is clearly not first best, it is still preferable to a situation of no HOV lane.

Alternative direct congestion mitigation policies, such as, for instance, pedestrians-only area, are clearly suboptimal, at least from the perspective of pure congestion mitigation.

Introduction

Congested urban transportation networks are examples of complex systems in which users, that is, travelers, interact with infrastructure. The behavior of the users is, typically, delineated as being either that of user-optimization or system-optimization based, respectively, on [Wardrop's, 1952](#) two principles of travel behavior. In the case of the user-optimization, each user "selfishly" selects his own optimal route of travel from an origin to a destination with an equilibrium being achieved when no user has any incentive to alter his travel path. The governing equilibrium conditions state that all used paths, that is, those with positive flow, connecting each origin/destination pair of nodes of travel will have equal and minimal travel cost. In the case of system-optimization, there exists a central controller that routes the traffic flow from origin nodes to destination nodes so that the total cost in the transportation network is minimized. Importantly, in congested transportation networks, the cost (usually reflecting travel time although the cost may be generalized to include monetary cost, risk, etc.) on a link is an increasing function of the volume of the traffic flow on the link.

In 1968, Dietrich Braess in his classic paper, written in German, identified the possibility of the occurrence of counterintuitive behavior in user-optimized transportation networks. The paper was inspired by a seminar delivered by W. Knoedel in Muenster in 1967 when Braess was 29 years old (see [Nagurney and Boyce, 2005](#)). Specifically, he constructed a transportation network example consisting of a single origin/destination pair of nodes and two parallel paths, such that, when expanded with the inclusion of an additional link, which provided another route option for the travelers, the result was an increase in travel cost for all the travelers! The demand and original link cost functions had not changed. This surprising discovery was in contrast to conventional wisdom in that the addition of a link, which yields another route option for travelers between their origin/destination pair, would make each user better-off in terms of travel cost/time. This counterintuitive phenomenon has become known as the Braess paradox.

What is also remarkable is that, as discussed in [Nagurney and Boyce \(2005\)](#), at the time that Braess described this paradoxical behavior, he was unaware of Wardrop's two principles of travel behavior and their rigorous mathematical formulation given in the book by [Beckmann et al. \(1956\)](#). Nevertheless, and this is also noteworthy, the Braess paper described two different concepts of traffic network utilization that correspond, respectively, to analogues of system-optimization and user-optimization. It is important to mention that the terms "user-optimization" and "system-optimization" were subsequently coined by [Dafermos and Sparrow \(1969\)](#). The [Braess \(1968\)](#) paper was followed by that of [Murchland \(1970\)](#), who elaborated upon the Braess paradox, reflected upon it in the context of [Beckmann et al. \(1956\)](#) and [Beckmann \(1967\)](#), and brought it to the attention of the English speaking community.

This paradox has come to fascinate researchers and practitioners in transportation and related fields, in which decentralized behavior in congested networks is relevant, such as in computer science, as in the case of the modeling of telecommunication networks and the Internet (see [Korilis et al., 1999](#); [Nagurney et al., 2007b](#); [Roughgarden, 2005](#); [Roughgarden and Tardos, 2002](#)); in electrical engineering, for the study of power systems ([Blumsack et al., 2007](#); [Cohen and Horowitz, 1991](#)) and electronic circuits (cf. [Nagurney and Nagurney, 2016](#)), as well as in physics in the case of mechanical ([Cohen and Horowitz, 1991](#)) and fluid systems ([Calvert and Keady, 1993](#)); in biology, as in metabolic networks (see [Motter, 2010](#)), ecosystems ([Sahasrabudhe and Motter, 2011](#)), and targeted cancer therapy ([Kippenberger et al., 2016](#)), and, surprisingly, in sports analytics as in the study of sports teams, where the Braess paradox analogue corresponds to the removal of a player resulting in better team performance (cf. [Gudmundsson and Horton, 2017](#); [Skinner, 2011](#)). Because of the interest from multiple disciplines, a translation of the paper from German to English was published by [Braess et al. \(2005\)](#). The foreword by [Nagurney and Boyce \(2005\)](#) to the translated paper contains additional background of how Braess came up with the counterintuitive phenomenon, along with clarifications of some of the concepts and terms.

Figure 1 The Braess paradox example topology.

The Classic Braess Paradox

The classic Braess paradox example is as follows. Consider first the four-node transportation network as illustrated by the left-most network in **Fig. 1**.

There is a single origin/destination (O/D) pair of nodes $w = (1, 4)$. A traveler on this network can travel on one of two paths: on path p_1 consisting of the links: a, c or on path p_2 consisting of the links: b, d . We denote the flows on the links by: f_a, f_b , and so on, and their respective user link costs by: c_a, c_b , etc. Specifically, in this network the user link cost functions are: $c_a(f_a) = 10f_a, c_b(f_b) = f_b + 50, c_c(f_c) = f_c + 50, c_d(f_d) = 10f_d$.

Let the travel demand d_w be 6, which represents 6 vehicles of travel per unit time. We denote the flow on a path p by x_p so here we have x_{p_1} and x_{p_2} .

The conservation of flow equations ensure that the demand for each O/D pair is satisfied by the flows on paths that connect the O/D pair and that the link flows capture the flows that utilize the particular link. Specifically, the equations state that the sum of flows on paths connecting each O/D pair must be equal to the demand for that O/D pair and that the flow on a link must be equal to the sum of flows on the paths that contain/utilize that link.

Clearly, under user-optimizing behavior, the resulting equilibrium path flow for the first network is: $x_{p_1}^* = x_{p_2}^* = 3$, with incurred user path costs of: $C_{p_1} = C_{p_2} = 83$. No traveler has any incentive to switch her path since that would result in a higher cost for her. This result is apparent since the costs on the two paths are: $C_{p_1} = c_a + c_c = 10f_a + f_c + 50$ and $C_{p_2} = c_b + c_d = f_b + 50 + 10f_d$ and, therefore, the travelers at a demand of 6 will equally distribute themselves between the two paths, yielding the equilibrium path flows: $x_{p_1}^* = 3$ and $x_{p_2}^* = 3$ and incurred equilibrium flows: $f_a^* = f_b^* = f_c^* = f_d^* = 3$, with user link costs: $c_a = c_d = 30$ and $c_b = c_c = 53$.

Consider now the addition of a new link, e , joining node 2 with node 3 as in the right-most network in **Fig. 1**. Let the user link cost c_e on link e be

$$c_e(f_e) = f_e + 10.$$

A user on the expanded transportation network now has three path options: the original two paths, p_1 and p_2 , plus the new path $p_3 = (a, e, d)$. The equilibrium flow pattern on the first network will no longer yield an equilibrium for the second network. Indeed, observe that although the costs on paths p_1 and p_3 would be 83, the cost on the new path, C_{p_3} , if it is not used, that is, it has zero flow, would be 70. Clearly, some travelers, under user-optimization, would switch from paths p_1 and p_2 to path p_3 since the cost on path p_3 is less than 83.

Typically, we apply algorithms (cf. Nagurney, 1999; Patriksson, 2004) to determine the user-optimized/equilibrium flows in transportation networks, since they are usually large-scale and a priori it is difficult to identify which paths will and will not be used. In this example, because of its size, we can calculate the solution explicitly. We will assume that all paths are used. Hence, we can set up a system of equations making use of the following:

$$C_{p_1} = C_{p_2} = C_{p_3}$$

and

$$x_{p_1}^* + x_{p_2}^* + x_{p_3}^* = d_w = 6.$$

Furthermore, we know that according to the conservation of flow equations for the link and path flows:

$$f_a^* = x_{p_1}^* + x_{p_3}^*$$

$$f_b^* = x_{p_2}^*$$

$$f_c^* = x_{p_1}^*$$

$$f_d^* = x_{p_2}^* + x_{p_3}^*$$

$$f_e^* = x_{p_3}^*.$$

Hence, we can rewrite that user costs on paths as functions of path flows as follows

$$C_{p_1} = 10(x_{p_1}^* + x_{p_3}^*) + x_{p_1}^* + 50 = 11x_{p_1}^* + 10x_{p_3}^* + 50,$$

$$C_{p_2} = x_{p_2}^* + 50 + 10(x_{p_2}^* + x_{p_3}^*) = 11x_{p_2}^* + 10x_{p_3}^* + 50,$$

$$C_{p_3} = 10(x_{p_1}^* + x_{p_3}^*) + x_{p_3}^* + 10 + 10(x_{p_2}^* + x_{p_3}^*) = 10x_{p_1}^* + 10x_{p_2}^* + 21x_{p_3}^* + 10.$$

Using then the demand conservation of flow equation above and substituting, we obtain a system of equations, the solution of which yields the equilibrium flow pattern on the expanded network of: $x_{p_1}^* = x_{p_2}^* = x_{p_3}^* = 2$, with the incurred equilibrium path travel costs:

$$C_{p_1} = C_{p_2} = C_{p_3} = 92!$$

Thus, the addition of a new link makes every user worse-off in that each traveler in the expanded network incurs a higher travel cost than before!

It is important to note that the Braess paradox can only occur under user-optimization and never under system-optimization. Indeed, under system-optimization, in the second network in Fig. 1, only the original paths p_1 and p_2 would be used. It is important to emphasize that tolls can be assigned so that the system-optimizing flow pattern is at the same time user-optimizing; see Dafermos and Sparrow (1971) and Bergendorff et al. (1997). In particular, if one assigns link tolls as follows: toll on link a , $r_a=30$; toll on link b , $r_b=30$, with link tolls: $r_c=3$, $r_d=30$, and $r_e=30$, then travelers on the second network in Fig. 1 will independently distribute themselves according to the system-optimized flow pattern. The formula for tolls, in this case, due to Dafermos and Sparrow (1971), is $r_l = \hat{c}_l(f_l) - c_l(f_l)$ with the marginal total cost $\hat{c}_l$ and the user link cost c_l evaluated at the system-optimized flow pattern for all links l in the network and $\hat{c}_l = c_l \times f_l$ corresponding to the total cost on link l .

Generalizations of the Classic Braess Paradox and Related Paradoxes in Transportation

This counterintuitive example has given rise to many questions and the examination of under what conditions and scenarios the Braess paradox may arise. For example, in the classic example the travel demand $d_w=6$. Would the Braess paradox still occur under different values for the travel demand? Pas and Principio (1997) addressed this question and showed that the Braess paradox occurs only if the demand for travel falls within a certain intermediate range of values, specifically, if $2.58 < d_w < 8.89$. Interestingly, under low levels of demand only the new path p_3 is used and the paradox does not occur, whereas at higher levels of demand only the two original paths are used and the Braess paradox also does not occur. Subsequently, Nagurney et al. (2007b), utilizing connections between transportation and telecommunication networks, constructed a dynamic model of the Internet using evolutionary variational inequalities, and cast (cf. Fig. 2) the Pas and Principio results into a Braess paradox with time-varying demands, establishing the same results, but showed also that the curve of path flow equilibria is unique and that the equilibrium trajectories are continuous. Pas and Principio (1997) also showed, when examining linear, separable user link cost functions of the form as in the classic Braess paradox that, whether or not the paradox occurs, depends on the conditions of the problem; namely, the parameters of the link user cost functions.

Pas and Principio (1997) further suggested that, under higher levels of demand, the Braess paradox may not occur. Subsequently, Nagurney (2010) considered more general user link cost functions, which could be nonlinear, as well as asymmetric in that $\partial c_a(f)/\partial f_b \neq \partial c_b(f)/\partial f_a$, for all links a, b in the network, where f is the vector of link flows. In her paper, she considered the hypothesis that, in congested networks, the Braess paradox may “disappear” under higher demands, and proved this hypothesis by deriving a formula that provides the increase in demand that will guarantee that the addition of that new route will no longer increase travel cost since the new path will no longer be used. This result was established for any network in which the Braess paradox originally occurs and suggests that, in the case of congested, noncooperative networks, of which transportation networks are a prime example, a higher demand will negate the Braess paradox. At the same time, this finding shows that extreme caution should be taken in the design of network infrastructure, including transportation networks, since at higher demands, new routes/pathways may not even be used.

Steinberg and Zangwill (1983) considered linear separable user link cost functions and provided necessary and sufficient conditions, under reasonable assumptions, for the Braess paradox to occur in a general transportation network. They concluded that the Braess paradox is about as likely to occur as not occur.

While the classical example of the Braess paradox uses cost functions that are of the form: a fixed term plus a term proportional to the flow, other possible cost functions have been mathematically investigated in transportation networks, including the Bureau of Public Roads cost function (see Sheffi, 1985), which has a term quartic in the flow. The Braess paradox has been examined under such functions by LeBlanc (1975), Frank (1981), and Bloy (2007). Dafermos and Nagurney (1984a) demonstrated how, in terms of

Figure 2 Equilibrium trajectories of the Braess network with time-dependent demand.

traffic networks with general (asymmetric) user link cost functions, the addition of a route connecting an origin-destination pair that shared no links with any other route in the network, could never result in the Braess paradox. Moreover, the authors provided explicit formulae for the effects of cost function and demand changes on the incurred equilibrium path flows and path travel costs. The generalization of user link cost functions from separable, as well as symmetric ones, to asymmetric ones, made use of the formulation of the governing equilibrium conditions as a variational inequality problem (Dafermos, 1980; Nagurney, 1999; Smith, 1979). User-optimized networks with symmetric user link cost functions, in contrast, could be reformulated and solved as optimization problems (cf. Beckmann et al., 1956; Dafermos and Sparrow, 1969).

Hallefjord et al. (1994), in turn, presented paradoxes in transportation networks in the case of elastic demand, rather than fixed demands as in the original Braess paradox example. The authors noted that, in the case of elastic travel demand, it is not apparent what a paradoxical situation is, and in the elastic demand case there is a need for characterizations of different paradoxes. An example is provided in which total flow (demand) decreases while travel time increases due to the addition of a new link to the network, with this being a rather extreme type of paradox. Another highlighted paradox is when the network “improvement” leads to a reduction in the social surplus.

As noted in Boyce et al. (2005), sensitivity analysis is also essential to the effective planning/design of transportation networks and the Braess paradox motivated much of the subsequent research in sensitivity analysis and networks. Dafermos and Nagurney (1984b), for example, used the variational inequality formulation of traffic network equilibrium with fixed demands to provide directional effects of link cost function changes and to demonstrate that small changes in the data yielded small changes in the resulting equilibrium link flows. For other sensitivity analysis results in the context of traffic network equilibrium problems, see, e.g., Tobin and Friesz, 1988; Frank, 1992; Yang, 1997; Patriksson, 2004, and the references therein.

It is worth pointing out additional related paradoxes to that of the Braess paradox in transportation. Sheffi and Daganzo (1978) presented a counterintuitive result that may occur when stochastic traffic assignment methods are used; see also Yao and Chen (2014). Fisk (1979) constructed examples showing that both origin to destination and global travel costs may decrease for an O/D pair as a result of an increase in travel demands for another O/D pair. Subsequently, Fisk and Pallotino (1981) provided network examples for the city of Winnipeg, demonstrating that the Braess paradox could occur in real world networks. Yang and Bell (1998) introduced a new paradox associated with network design problems via a simple network example in which the addition of a new road segment to a road network may reduce the potential capacity of the network. Nagurney (2000) identified emission paradoxes; in particular, three distinct ones that can occur in congested urban transportation networks in terms of the total emissions generated. These emission paradoxes reveal that so-called improvements to the transportation network may result in increases in total emissions generated.

Zhang et al. (2016) considered the Downs–Thomson paradox. The Downs–Thomson paradox, named after Downs (1962) and Thomson (1977), suggests that highway capacity expansion may produce counterproductive effects in a two-mode (auto and transit) transportation system. Specifically, Zhang et al. (2016) reexamined the paradox when certain assumptions are relaxed while retaining the usual assumption that there is no congestion interaction between the modes. Arnott and Small (1994) reviewed the Downs–Thomson paradox and also explicated the Pigou–Knight–Downs paradox, in which expanding road capacity may elicit its own demand with no improvement in congestion.

Observations in Transportation Systems

While it may be challenging to accurately control the demand and to measure the travel time (cost) on real road systems with actual drivers, there are several documented examples of the “inverse” of the Braess paradox being observed in a transportation network after a link was removed. In other words, travel time improves after the removal of a link. Many of these examples/instances have been written up in the popular press.

For example, [Kolata \(1990\)](#), writing in *The New York Times*, noted that, in 1990, on Earth Day, the New York City’s Transportation Commissioner decided to close 42nd Street, and to “everyone’s surprise” no historic traffic jam was generated and traffic flow actually improved. She stated that this may be a real-world example of the Braess paradox. That same year, [Cohen and Kelly \(1990\)](#) constructed an example where a Braess-type paradox occurs in a queuing network. The authors cited the paper by [Knodel \(1969\)](#) that noted that the City of Stuttgart had tried to ease downtown traffic by adding a new street. However, congestion only worsened, and hence, in desperation, the authorities closed the street. The result was that the traffic flow improved.

In 1999, according to [Vidal \(2006\)](#), one of the three main traffic tunnels in Seoul, the capital of South Korea, was closed for maintenance. Surprisingly, the result was not chaos and traffic jams, but, rather, the traffic flows improved. Inspired by their experience, Seoul’s city planners, subsequently, demolished a major motorway leading into the heart of the city and experienced the same strange result, with the added benefit of creating a 5-mile long, 1000 acre park for the local inhabitants (see also [Baker, 2009](#)).

And, in 2009, in an ambitious project in NYC, a part of Broadway in mid-Manhattan was converted to a pedestrian plaza and vehicular travel banned (see [Grynbaum, 2010](#)). This redesign of infrastructure was made permanent and has lasted even past the original mayoral administration of Michael Bloomberg. Traffic flows, in parts, improved.

Other Systems that May Exhibit Braess Paradox Behavior

There exists a plethora of realizable physical systems that may exhibit Braess paradox behavior and, in certain such physical systems, the demand (total flow) may be controllable and the laws of physics ensure that the decentralized network is, in fact, user-optimized. In contrast to congested transportation networks, users are no longer travelers, but correspond to electrons in electric power systems, or to fluid molecules (water, oil, etc.) in the case of pipeline networks, etc. Such analogues of transportation networks are quite natural and we note that [Beckmann et al. \(1956\)](#) hypothesized that electric power generation and distribution networks would behave like congested urban transportation networks. This hypothesis was substantiated by [Nagurney et al. \(2007a\)](#); see also the references therein. Moreover, fluid flow models have been developed for traffic; see, e.g., [Lighthill and Whitham \(1955\)](#), [Herman et al. \(1959\)](#), and [Herman and Prigogine \(1979\)](#).

For example, [Cohen and Horowitz \(1991\)](#) suggested that it might be possible to create mechanical, electrical, fluid, and thermal systems that exhibit counterintuitive behavior when a physical component was added. As an illustration of such a mechanical system, they showed that a weight hanging from a coupled pair of springs with safety strings can rise, rather than fall, when the taut coupling string is cut. They also demonstrated that an electrical network with a topology of the [Braess \(1968\)](#) example and consisting of ideal passive components (resistors and zener diodes) can exhibit the counterintuitive behavior of the voltage rising across the network when an additional branch (link) is added.

Details of a spring network that exhibited the Braess paradox were delineated by [Penchina and Penchina \(2003\)](#). The authors also noted that the only requirement for the spring network to exhibit the paradox is that the springs must shrink more than the safety strings stretch. [Peters and Vondracek \(2012\)](#) extended the experiments to include variation in the mass and the spring constant.

[Witthaut and Timme \(2012\)](#) studied the addition of single links in a class of oscillator networks that model modern power grids on coarse scales. They showed that, while, on the average, the additional links stabilized the network, the addition of specific new links could decrease the total grid capacity and, thereby, decrease or even destroy the stability of the grid. In addressing the question of reliability of the power grid, [Blumsack et al. \(2007\)](#) noted that in a power network with the classic Braess topology, adding a line (link) might result in another line becoming capacity limited, which would affect the optimal power dispatch and result in higher costs.

The idealized electrical circuit, as described by [Cohen and Horowitz \(1991\)](#), was converted to a real electrical circuit by [Nagurney and Nagurney \(2016\)](#), who used electric circuit theory to develop matrix equations to describe the voltage drop (equivalent to cost) as a function of the circuit elements and current flow (demand). The authors then used this formulation to build a circuit using standard electrical components in which the voltage and currents could be measured. In addition to constructing an actual physical circuit whose voltage drops were functionally similar to the cost functions suggested by Braess in his classic example, [Nagurney and Nagurney \(2016\)](#) also constructed and measured the parameters of a circuit with more general voltage drops that exhibited behavior consistent with the Braess paradox.

The concept of the Braess paradox was also investigated by [Pala et al. \(2012\)](#) in semiconductor networks, whose transport properties are governed by quantum physics. The authors demonstrated theoretically that congestion plays a key role in the occurrence of the Braess paradox in such networks.

Both macro- and microfluidic systems can exhibit behavior analogous to the Braess paradox. [Ayala and Blumsack \(2013\)](#) considered a macrofluidic system, as in natural gas distribution networks, and studied the existence of paradoxical effects, relevant to network design. In their analysis, the simple addition of a pipe to transport gas may not necessarily increase the ultimate

transmission capacity. In terms of a microfluidic system, Case et al. (2019) showed that both the flow rate in a system with the classic Braess topology and the direction of the flow in the linking channel are dependent on the input pressure.

It is clear that, more than 50 years since the publication of the paper by Braess (1968), the paradox and the associated gleaned insights into decentralized noncooperative behavior remain relevant, continue to fascinate, and to inspire research in transportation. Its applicability to practice also continues to this day, in transportation network planning and design. Finally, the Braess paradox has served as a bridge for broadening perspectives in other scientific disciplines by enabling the advancement of the theory of the behavior of complex network systems with a vast range of important applications.

INTRODUCTION

Roger Vickerman

In an increasingly globalized world, despite reductions in costs and time, transportation has become even more important as a facilitator of economic and human interaction; this is reflected in technical advances in transportation systems, increasing interest in how transportation interacts with society and the need to provide novel approaches to understand its impacts. This has become particularly acute with the impact that Covid-19 has had on transportation across the world, at local, national, and international levels. This Encyclopedia brings a cross-cutting and integrated approach to all aspects of transportation from work in many disciplinary fields, engineering, operations research, economics, geography, and sociology to understand the changes taking place.

Transportation is both influenced by, and an influencer of, changes in the economy and society. Increasing speeds have reduced journey times and made the world a smaller place as globalization has affected both where people live and work and from where they source their goods and materials. Increasing volumes of traffic, often on old and life-expired infrastructure, lead to congestion and delays. Constraints on public budgets have led to increasing pressure on the private sector to fund improvements requiring new and innovative financial solutions. While there are clear differences in the nature of the pressures felt in the developed and less developed economies, there is an increasing recognition that in all societies, there is an accessibility problem such that certain groups become disadvantaged by the lack of access to reliable and cost-effective transport. While the problems are clearly multidimensional, research on transportation is often constrained by single disciplinary approaches and this carries over into the practice of transport planning and policy. The Encyclopedia cuts across these artificial boundaries by taking an approach that emphasizes the interaction between the different aspects of research and aims to offer new solutions to understand these problems. Each of the nine sections is based around a familiar dimension of work on transportation, but brings together the views of experts from different disciplinary perspectives. Each section is edited by an expert in the relevant field who has sought chapters from a range of authors representing different disciplines, different parts of the world, and different social perspectives. In this way, the work is not just a reflection of the state of the art that serves as a starting point for researchers and practitioners, but also a pointer toward new approaches, new ways of thinking, and novel solutions to problems.

The nine sections are structured around the following themes: Transport Modes; Freight Transport and Logistics; Transport Safety and Security; Transport Economics; Traffic Management; Transport Modeling and Data Management; Transport Policy and Planning; Transport Psychology; Sustainability and Health Issues in Transportation. Some of the chapters provide a technical introduction to a topic while others provide a bridge between topics or a more future-oriented view of new research areas or challenges. While there is guidance to cross-referencing between chapters, readers are encouraged to explore the tables of contents of all the sections to get a full understanding of the issues. Much of the Encyclopedia was completed before the Covid-19 pandemic and clearly this will have changed the situation in many areas covered by this work; the advantage of this type of reference work is that relevant updates will be possible in future editions.

The Encyclopedia has only been possible because of the cooperation of a large number of people. Robert Noland, Georgina Santos, Xiaowen Fu, and Dick Ettema served as an Editorial Advisory Board identifying possible editors of sections and advising on the overall structure. The Section Editors, Edoardo Marcucci, Kevin Cullinane, Per Garder, Maria Börjesson, Edward Chung, Chandra Bhat, Maria Attard, and Carlo Prato,

carried out the work of identifying potential authors of individual chapters, commissioning these, encouraging authors and reviewing drafts. More than 600 authors and co-authors of chapters are, however, ultimately responsible for the success of this venture. Thanks are also due to the key people at Elsevier, particularly the Publishers, Andre Wolff and Oliver Walter, and the Project Managers, Sophie Harrison and Natalie Bentahar; they have shown exemplary patience over more than 3 years in bringing this work to fruition.

LIST OF CONTRIBUTORS TO VOLUME 2

Claes Tingvall
AFRY, Solna, Sweden

Anders Lie
Chalmers University of Technology, Gothenburg, Sweden

Robert A. Scopatz
VHB, Inver Grove Heights, MN, United States

James E.W. Roseborough
OCAD University, Toronto, ON, Canada

CONTENTS OF ALL VOLUMES

<i>Editorial Board</i>	<i>v</i>
<i>Introduction</i>	<i>vii</i>
<i>Contributors to Volume 2</i>	<i>ix</i>

VOLUME 1

Introduction to Transportation Economics	1
Market Failures and Public Decision Making in the Transport Sector <i>Bruno De Borger and Stef Proost</i>	2
Demand for Freight Transport <i>José Holguín-Veras and Diana G. Ramírez-Ríos</i>	7
Cost Functions for Road Transport <i>José Manuel Vassallo</i>	13
Future of Urban Freight <i>Russell G. Thompson</i>	20
Operation Costs for Public Transport <i>Marco Batarce</i>	26
Natural Monopoly in Transport <i>André de Palma and Julien Monardo</i>	30
Freight Costs: Air and Sea <i>Yulai Wan and Dong Yang</i>	36
Transport Production and Cost Structure <i>Ricardo Giesen and Darío Farren</i>	46
The Concept of External Cost: Marginal versus Total Cost and Internalization <i>Sofia F. Franco</i>	56
Value of Time <i>John J. Bates</i>	67
Valuation of Carbon Emissions <i>Svante Mandell</i>	72
Valuation of Travel Time Variability Using Scheduling Models <i>Katrine Hjorth</i>	76

Value of Crowding <i>Daniel Hörcher</i>	84
What Drives Transport and Mobility Trends? The Chicken-and-Egg Problem <i>Nathalie Picard</i>	89
Pricing Principles in the Transport Sector <i>Bruno De Borger and Stef Proost</i>	95
Long-Run Versus Short-Run Valuations <i>Stefanie Peer</i>	102
Value of Noise <i>Jon P. Nelson</i>	106
The Value of Life and Health <i>Henrik Andersson</i>	114
The Value of Security, Access Time, Waiting Time, and Transfers in Public Transport <i>Raquel Espino, Juan de Dios Ortúzar, and Luis I. Rizzi</i>	122
Demand for Passenger Transportation <i>Kenneth A Small and Robin Lindsey</i>	127
Real-World Experiences of Congestion Pricing <i>Charles Raux</i>	134
Distributional Effects of Congestion Charges and Fuel Taxes <i>Jonas Eliasson</i>	139
The Bottleneck Model <i>Dereje Abegaz and Yili Tang</i>	146
Dynamic Congestion Pricing and User Heterogeneity <i>Kathrin Goldmann and Gernot Sieg</i>	150
Economics of Parking <i>Daniel Albalade and Albert Gragera</i>	159

Introduction to Transportation Safety and Security

Per Gårder, Department of Civil and Environmental Engineering, University of Maine, Orono, ME, United States

© 2021 Elsevier Ltd. All rights reserved.

The reason we travel is a need or desire to get somewhere else. People typically prioritize how to get to their destination quickly and comfortably. Most of the time, it is assumed that we will get there safely. But as parents, we may worry about our children's safety and in a snow storm we may worry about our own safety. However, as a society, we should be concerned about the lack of safety for all of us, not least the elderly and the disabled, in our road transport system. We are far from safe as pedestrians, bicyclists, or motorists. The perceived safety and the objective safety often do not coincide. Lots of people fear to fly in big jets but do not worry about driving to the airport.

This section of the encyclopedia has an emphasis on transportation safety, and how safety is managed for all modes of transport. But it also has articles that deal with personal security, such as the risk of being assaulted—from verbally abused to raped or murdered—while traveling and how to evacuate areas safely during weather events such as hurricanes and flooding, events that are becoming increasingly common because of climate change. An area that is not directly dealt with in this section is how infectious diseases, such as Covid-19, can spread from continent to continent by airplanes and ships, and how local transmission can be facilitated by public transportation. Also, breathing polluted air while traveling can certainly make us “unsafe.” Other parts of the Encyclopedia deal with such issues. In general, the overall relationship between transport and health has become increasingly acknowledged and Vision Zero programs—where the goal is to eliminate death and serious injury—are discussed in this section with respect to accidents and crashes. But for a transportation system to be safe, it also has to guarantee personal security and make sure we do not get exposed to unhealthy emissions, be they from that transportation system itself or from other sources.

The chapters, in this section present a range of views across these topics. Perspectives from and policies in North America, Europe, Asia, Australia, and Africa are brought up, but some articles are limited to practices in only a few countries. However, implications can and should be drawn to how these practices could be transferred to other regions, not least to less developed nations. All the articles are based on current state-of-the-art research. Some topics are of philosophical nature whereas others deal with actual government policies and yet others with how design details may affect the safety of users. Many of the chapters have cross-cutting themes with chapters in other sections of the Encyclopedia, especially those dealing with Transport Planning and Policy, and Sustainability of Transport Systems, but also with Psychology, and readers are encouraged to explore these to gain a fuller understanding of safety and security issues.

The Concept of “Acceptable Risk” Applied to Road Safety Risk Level

Claes Tingvall^{*,†,‡}, Anders Lie[†], ^{*}AFRY, Solna, Sweden; [†]Chalmers University of Technology, Gothenburg, Sweden; [‡]Monash University Accident Research Centre, Melbourne, VIC, Australia

Background

The concept of risk is used extensively in the community describing the possible or observed rate of an occurrence for a variety of events. Risk can apply to the probability of change to aspects relating to the economy, health, climate, safety or anything else. It can be seen as the normal or abnormal chance of a certain outcome or scenario. Risk can also denote the probability or chance of us as individuals being exposed to a road traffic crash with a certain outcome.

The risk is often described as a population risk, or a risk to be injured or maybe killed as a user of a certain kind of vehicle or mode of mobility. These two risk examples can be seen as both the societal risk and as the risk for any one citizen exposing him or her to a certain type of road traffic. We can also refer to these risks as being seen from a macro or microperspective. In the macroperspective, we “know” that a large number of people will be killed in roadway crashes in X-land in the next year. But, in the micro perspective, seen from one individual’s viewpoint, it is very unlikely that he or she will be killed in the next year.

The more intriguing or maybe philosophical question is who we address with this risk estimate. Is it society as a sort of a provider of the road transport system or is it the sum of individuals that collectively are willing or maybe are forced to take the risk?

It is clear that society consider any road user, or anyone appearing on a road, as an active individual with a legal responsibility to minimize risk. Risky behavior, irrespective of age, situation or role, is illegal from a legal standpoint according to the Vienna Convention. The Vienna Convention is an international treaty designed to facilitate international road traffic and to increase road safety by establishing standard traffic rules among the contracting parties. The convention was agreed upon at the United Nations Economic and Social Council’s Conference on Road Traffic in Vienna in 1968 and came into force in 1977. It replaces previous road traffic conventions, most notably the 1949 Geneva Convention on Road Traffic, which was ratified by 98 countries. The Vienna Convention has been ratified by 78 countries, and those who have not ratified it are still parties to the 1949 Geneva Convention if they had ratified that. Canada, Ireland, and the United States are examples of such countries. The Vienna Convention gives guideline for national road traffic rules and is detailed in what responsibilities that falls on the road user, but does not specify any rules for the providers of the system, other than signs and markings.

Any crash, in theory, can be tracked to an individual and his or her “illegal” behavior. This makes the road user a primary agent, irrespective of the technical solutions, design of roads and streets as well as vehicles. Implicitly, this means that the collective of road users are the prime source of actions and behavior resulting in crashes, injuries and deaths. Society, through the providers of the road transport system, can decide to set up requirements for vehicle standards and for road design, in order to reduce risk. One requirement for doing so is, however, that the action taken should be “cost-effective,” albeit in a broad sense and taking into account both budgetary consequences and the willingness pay or act among citizens (Elvik, 1999). It is implicitly or through explicit policies normal to consider an investment or action to be ineffective if the costs, in a broad sense, are larger than the benefits.

Despite rules of the road, the resulting consequences of the individuals’ and society’s way to deal with risk can be seen as disappointing. Each year, more than 1 million individuals are killed in road crashes across the globe (Academic Expert Group, 2019). This corresponds to an annual risk of death of around 175 deaths per million humans, or around 9000 per million lifetime risk, which is the same as 0.9% probability that an individual will be killed in a road crash. In countries with the lowest numbers of deaths, corresponding results are 20 deaths per million human, annually, and 2500 deaths per million lifetime risk. The difference between countries with the lowest risk and the highest risk seems to be in the magnitude of 10–15 times.

In other transport modes, like aviation or railway, the risks to the passengers are at a very different level compared to road traffic. In civil aviation, the level is in the magnitude of 300 deaths per year across the globe. Seen as a population risk, we have less than 0.5 death per million annually. When we measure against travel distances or number of passengers, the difference between road and aviation is smaller but still substantial. Instead of a risk ratio between road and aviation based on population (3000–4000 times) it would be in the order of 1000 times.

The Concept of Acceptable Risk

The varying risk levels in the transport sector, and the risk levels in other sectors, ask for a deeper analysis of the reasons for why this has been considered acceptable. Why has it not created a sense of human catastrophe with such risks in the road transport sector? One hypothesis would be in line with the concept of acceptable risk (AR) (Fischhoff et al., 1981; Hunter and Fewtrell, 2001).

There are two general principles for setting or accepting a level of AR (Hunter and Fewtrell, 2001). In activities where humans themselves judge their personal risk, there are clear possibilities to generate what seems to be acceptable from the participation in such activities. This is sometimes called a “revealed preference risk.” In the literature, there are a number of suggestions on what influence such acceptance. The level of self-control seems to be one of them. The consequences of a failure or mistake by the individual involved in the activity as well, and if the risk is voluntary or not. Implicitly, a revealed risk is the accumulated risk perception or risk behavior of individuals in relation to their own life and health. It seems that we use the revealed AR as the norm in road traffic management, investments, and solutions.

The other general principle is about setting a predefined AR. This is common in technical systems, medicine, occupational health and safety, nuclear power, aviation and railway, etc. A rationale for predefined AR is that the activity or system is “manmade.” Implicitly there is also an understanding of a predefined risk as a risk someone else is exposed to by a system, activity or action taken in relation to someone else’s life and health.

When predefined an AR, there are both similarities and differences between sectors. What they have in common is that a predefined risk is generally very low, and measurable. Below are a few examples from different sectors.

One example that is relevant for the road transport sector would be the railway system. Here, we can find not only an overall AR but also the AR broken down to subsystems and components.

Setting a Predefined AR for the Road Transport System

It seems to be quite simple to set a predefined AR for the road transport system by adopting the general level from systems like aviation and railroads. The more serious question is what consequences this would have on the design, function, and access to road transport.

The examples from railway and aviation are both functional and relevant down to specific solutions and locations. The EU regulation on railway safety (EU regulation 352/2009 on common safety regulation on risk evaluation) seeks to standardize risk calculations on both known and new solutions. And there are AR levels predefined as well as a definition of safety. This definition is “freedom from unacceptable risk of harm.”

The “proposer” of a new solution needs to either compare the solution to other comparable solution or to undertake an explicit risk estimation of the proposed solution. The national risk level for railroads is supposed to be smaller than 10^{-9} per operating hour for any technical failure that would be safety sensitive. A new solution may not lead to that this level is exceeded. It seems that the AR also accounts for cases where we have a man–machine interface, that is, there is a human involved in the technical system.

A risk level of 10^{-9} failures per operating hour on the transport system, for each train-set or vehicle, would lead to one failure per 114,000 years of operation, or 8.8 failures per million vehicle hours. In practice, it is very hard to evaluate if this is met, but if we look at fatalities in the European rail system, there have been very few catastrophic crashes, not even one per year for each of the 28 member states. Eight people were killed in collisions as passengers of trains in 2015 and none in a derailment. If the EU population, 508 million in 2015, each traveled by train, on average, 10 min/day, and we have an AR level of 10^{-9} fatalities per person-travel-hour, rather than operating hour, we would accept 31 fatalities per year for EU-28, and, with 8 fatalities, we met the goal for 2015. The 10 min rail travel per time may be a high guesstimate, but as long as the average rail travel time is at least $8/31 \times 10 = 2.5$ min/day, the goal is met. On the other hand, more than 1700 people were killed as third party individuals by trains that same year. The victims were mostly car occupants or pedestrians on railway crossings; or simply individuals crossing railway tracks at locations with no regular railway crossing. If we apply the same AR for the roadway system, and assume people travel for one hour per day on average, we would accept 185 fatalities per year in all of EU-28. In reality Europeans spend less than an hour a day in cars, so a slightly lower number should be accepted. However, people also walk in traffic, and if we include pedestrian fatalities in the numerator, we could also include time spent in traffic walking, and one hour per day is probably a reasonable estimate. In reality 26,100 people were killed in roadway crashes in EU-28 in 2015. So, we have around 140 times more people killed on roadways in the EU than what is considered acceptable, and met, by the railway industry. And, the EU is certainly not alone here. Let us look at the US, using 2015 data. The US had around 321 million inhabitants that year and if everyone traveled one hour per day, we would accept up to 117 fatalities in the year if we use a risk level of 10^{-9} fatalities per travel hour. The actual number of fatalities was 35,092. That means we had a fatality risk on US roads in 2015 that was almost exactly 300 times the acceptable one for passengers in the rail system.

Implications and Consequences of Setting a Predefined AR Level for Road Traffic Safety

While it might be stated that the question of whether we should apply a revealed AR perspective or a predefined AR for road traffic safety is political or even philosophical. On the other hand, there is no doubt and some quite clear examples where the design and operation of the road transport system decide the risk level, rather than the users' choice of risk taking. Using a roundabout rather than a traditional intersection is one example. Replacing centerline striping on rural 2-lane highways with cable barriers is another example, and there are of course plenty of other examples. The question is though what would follow if we change from revealed to predefined AR? There would be a number of both real consequences as well as implications if we would set a predefined acceptable level. The most obvious would be to decide at what level it should be set, and for whom it would apply. It seems natural to choose the same level as for railway and aviation. At least this would be natural for passengers in cars, buses and alike. To passengers we would also add those in an automated vehicle, including third party road users outside an automated vehicle, in essence pedestrians, cyclists, etc.

But the implications would go far wider. Both design of infrastructure and vehicles would have to be chosen on the basis on a predefined risk level, meaning that only the best possible solutions would be used. And the kinetic energy, that is, speed, would have to be based on the predefined level.

Even if we decided to choose a predefined AR, and in reality this is the case for more or less the whole world, it would still be a question of how it should be applied to different parts of society. Would policy decisions, ethical rules or something else be enough? Or do we have to use the examples from aviation and railway to bring in legislation, duty of care, and require continuous improvement to change the way the system is operated?

Discussion

In this article, it is questioned whether we should consider a predefined AR level for road transportation, and if such adoption would be not only useful but also in fact logical. If we step away from the thought that the AR in road transportation is more or less revealed, we would be offered to take quite a large step in what the society can accept in terms of risk to human life and health.

On the other hand, the UN (Academic Expert Group, 2019), and many jurisdictions including the US, the EU, Australia etc. have already adopted Vision Zero (Lindberg and Håkansson, 2017) or Safe System which are nothing but predefined AR policies. But we still build roads and streets, design vehicles and operate transport services as if we still have revealed AR as our approach.

The transport policy seems to still be based on the economic theory of balancing mobility to safety, and that investments and initiatives must be economically sound. The economic theory seems to still see the road user as the agent, and that risks taken could be considered as the correct revealed risk.

One might describe road safety countermeasures that inflicts with humans as paternalistic and a sign of a “nanny state” (Eberhard, 2006). But it could easily be mirrored by the notion that protecting other human's life is a duty that has been around for thousands of years (Hippocrates 400 BC) and codified in legislation, ethical rules, and duty of care practices, and, as shown, also in the principles of predefined AR (Hunter and Fewtrell, 2001).

What it all comes down to is if road traffic safety performance is mainly generated by individuals making informed choices of their risk, or by professional providers of a road transport system caring for the citizens' life and health? It can be shown empirically (Hauer, 2015; Krafft et al., 2008; Lindberg and Håkansson, 2017) that design solutions of roads, streets and vehicles can have a dramatic effect on the risk of death and serious injury. And it can also be shown that some stakeholders in reality can get very close to zero deaths (Rizzi et al., 2019).

If we on large accept the role of the providers as the main agents for safety, it makes sense to adopt the principles of predefined AR, and at a level close to what seems to be normal, that is 1 per million population lifetime risk. (Since people spend, on average, roughly 1 h/day in traffic, over 80 years, a person would spend around 30,000 h in traffic and if we accept a risk of 10^{-9} per hour, we would accept a lifetime risk of 30 per million people. So 1 per million people is a high standard getting close to no one getting killed which is the ultimate goal of Vision Zero.) Globally, that could be translated to a maximum of less than 100 deaths per year. In comparison to the overall current level of 1.35 million deaths per year (Academic Expert Group 2019), the difference is gigantic. But it is a clear sign of how wrong we got it from the beginning; and maybe a sign that the recent socio-economic approach to balance mobility to safety was not only ethically misused but also detrimental to the life and health of humans.

Economic theory claim that there is a marginal decrease of the return of investment, that is, to save lives will come at a gradually higher cost of the community (Elvik, 1999). Even this argument has been proven to be false many times for road traffic safety (Tingvall and Lie, 2017). Saving lives today is cheaper than ever as new innovations are implemented (Rizzi et al., 2019), something the socio-economic models applied to mobility seem to have overlooked (Tingvall and Lie, 2017).

The implications of adopting a predefined AR for road traffic would be far going. First of all, mobility would come out as a function of safety (Haddon, 1970; Tingvall and Lie, 2017). Travel speed would have to be aligned with the road infrastructure design and the vehicles used. Secondly, a new product, road, street or vehicle would have to be designed on the basis of “best practice.” None can repeat a mistake or inferior design solution (Hauer, 2015) as this would be in breach of any idea behind a predefined AR.

The final question seems to be how we as a society in theory have abandoned the economic trade-off model by adopting a new policy that road crash fatalities should reach zero in the long term, while in practice, we are still using trade-off practices (Academic Expert Group, 2019)? How come we are still building inferior road infrastructure solutions, building cars without the best seat belts,

accepting speed and speed limits well beyond a zero policy? There is no clear answer to these questions, but maybe it is time to do what railway and aviation did many years ago. To not only adopt general principles but also to build a fence of rules, regulations, standards, and management practices that gradually improve the system. And to a level that is close to the golden standard of predefined AR.

The introduction of the 2030 Agenda principles for traffic safety (Academic Expert Group, 2019) goes quite far in recommendation for the allocation of responsibility for road transport safety. In relation to multinational corporations, it is recommended that their value chains should be transparent and reported as to what they expose employees, third-party citizens, and customers to in terms of safety. This is a starting point for such stakeholders to openly declare their targets and results. And it would come as a surprise if they would not accept a “zero tolerance” policy for their impact in the road transport system. And that would probably be in line with the global financial system expectations in relation to sustainability. As would a similar adoption of “zero tolerance” be expected for public procurement, which would mean that the economic logics would take a new turn in the history of traffic safety.

Introduction and Background

This article explains the case for using crash versus accident to describe whenever a motor vehicle collides with a person, another vehicle, or a roadside appurtenance, or follows a path of solitary destruction. While it is difficult to remain neutral on the word choice, the treatment here is intentionally unbiased and matter-of-fact so that readers may draw their own conclusions.

As a behavioral safety advocate and as someone who believes that words matter, my sympathies lie strongly in favor of using the word crash and I think my colleagues, and the world at large, agree. The truth is more complex. Some colleagues resist the change in terminology, some outright reject it, and some say it does not matter and we can use both words interchangeably. Notably, very few still advocate for accident as the universally accepted term. The shift in viewpoint is traceable back to William Haddon, the first Administrator of the National Highway Traffic Safety Administration (NHTSA) in the 1960s. The story goes that Haddon would fine anyone who used the word accident in a meeting. Thus, NHTSA has, right from the start, avoided the word accident. The logic is simple and straightforward. For those who prefer to use the term crash, they point out that accidental events must meet two criteria: (1) it is unintentional, and (2) it could not have been foreseen and thus was unavoidable. Of course, not everyone agrees that both criteria can be applied—the vernacular use of accident could point to any unintentional events or consequences regardless of how avoidable they are.

We will come back to consider this point with respect to traffic crashes, but should first reflect on how common the term accident is in industrial settings. Observers have pointed out that the term accident sets up an expectation of failure. If these events are unintentional, unforeseen, and (perhaps) unavoidable, we certainly will have more of them in the future (Smith, 2018). Historian Peter Norton traces the terminology in the context of industrial safety in the early 1900s, noting that companies sought to avoid blame by suggesting that harmful events were accidental, and certainly the companies themselves were not to blame. Automakers encouraged using the word accident to avoid the perception that cars and drivers were at fault in an era when they were routinely blamed for harmful events involving motor vehicles. In the 1920s, the auto industry even organized to change semantics to cast blame on pedestrians hit by autos and lobbied legislatures to that effect.

Traffic safety has a long history of officially using the word accident in our standard documents, including one of the pillars of the field, the American National Standards Institute (ANSI) D16 Manual on the Classification of Motor Vehicle Accidents (ATSIP, 2017). Up through the 7th edition the title and all relevant labels for events used the term accident. The 8th edition of ANSI D16 (released in 2017) has a new title, Manual on the Classification of Motor Vehicle Traffic Crashes, and the word crash replaces the word accident throughout. Chapter 1 of the latest edition of ANSI D16 begins with a note that the change from accident to crash was a deliberate step to avoid the implication that these events are unpreventable. It goes on to acknowledge that there are some who still use the term accident (including some state legislatures) and that treating the terms as synonyms by simply replacing accident with crash without any attempt to separate the avoidable from unavoidable events is not the intent.

Internationally, the terminology debate has not had quite the level of attention as it has in the United States; however, the discussion has had definite impacts. Transport Canada has adopted the term crash for their official traffic safety publications. The Traffic Injury Research Foundation (TIRF)—a Canada-based, independent, charitable road safety research institution—has promoted the switch from accident to crash (TIRF & DIAD, 2017). The *British Medical Journal* (BMJ) has, for most purposes, banned the use of accident (Davis and Pless, 2001). Outside these examples, however, it is easy to draw the conclusion that the concerns over terminology are not universal. It is also clear that not all share the same two-criterion definition of what makes an accident.

Are Crash and Accident Synonyms?

The answer is it depends on whom you ask. If the word crash focuses on the preventable nature of most of these events, and the word accident implies that they are unpreventable, the terms really do mean completely different things. By this view, the change in terminology in ANSI D16 truly recognizes a shift in understanding the nature of these events—that they are preventable. One source of contention is that some feel the implementation costs and the level of effort required to change existing legislation outweigh the benefit of adopting a more precise word. If no State had ever adopted the word accident in their traffic safety laws, it is likely that the debate would have been settled long ago. Since many states did write the definition of an accident into their traffic laws, changing that to use the crash term instead meets with some resistance. One of the easiest fixes proposed in these situations is to explain to legislators that crash is the preferred term, but that crash and accident are synonymous and thus a complete rewriting of all the laws to focus on the avoidable nature of crashes is not necessary—it is simplest to change just the word (and nothing else) in the laws. Proponents of the crash terminology are not happy with this solution, but would likely agree to the word-change-only approach in lieu of continued use of accident as a term of art. Others, the most avid proponents of the term crash, still argue that it is not synonymous with accident and that, should a state's laws imply that these events are truly accidental much more might need to change in the laws beyond just this single word choice. It's not an impossible task, but the level of effort is much higher. An effort that safety advocates clearly sees as worthwhile and necessary.

The Chain of Causality

Proponents of the term crash point to studies of crash causation as proof of their non-accidental nature. If we can find at least one causal factor in a crash, it makes sense that, were that cause removed or mitigated, the crash would not have occurred. We know that in more than 90% of crashes a human did something that contributed to the crash. Human-centered contributing factors include execution errors (mistakes in control inputs), misperceptions, errors in judgment, and lapses due to inattention and distraction. Then there are the more egregious errors such as choosing to drive while impaired by drugs or alcohol, and even the purposeful use of a vehicle as a weapon (and this includes aggressive driving). There are many other potential crash causes beyond the human factor—roadway conditions, adverse weather, debris, vehicle systems failures, and more. Ultimately, the percentage of crashes that can truly be labeled as accidental is quite small. The events were not caused some external, uncontrollable force that a prudent driver could not have dealt with.

That we can almost always identify multiple contributing factors for a crash means that it is not accidental based on the two criteria listed earlier. But, there are some limitations to even this perspective. In traffic safety and crash analysis, a forensic analysis is not typically performed to uncover the specific causes. Crash reconstruction arriving at a causal attribution is performed for only the most serious crashes involving a fatality, or where a serious criminal or civil case is likely. For the vast majority of crashes, the data indicate contributing factors based on a police officer's judgment. The determination of fault is not necessarily straightforward based on the crash report alone. The officer may indicate the most-at-fault person as a matter of departmental policy, but that does not mean there are not other contributing factors. It also does not mean that we can pinpoint the exact cause even if we know which person is most likely responsible. Even with complete and accurate data on crashes, cause can be an elusive concept. If this is true, then is there still room to conclude that all such result from the accidental confluence of multiple contributing factors? If the road had been less slick, the driver's speed might not have been a problem, if the driver had not been briefly blinded by the sun refracting off a dirty windshield, and so on.

Again, the simple answer is that most crashes can be traced back to the involved parties doing something wrong, including lacking the skill to operate the vehicle safely in the conditions they encountered. Inattention is not accidental—it is a choice. Distraction is a choice. Failure to keep the vehicle in good operating condition is a choice. Failure to slow down when the road is wet is a choice. Failure to use protective devices is a choice. Ultimately, while we might all agree that people rarely intend to do harm, it is difficult to call a crash unavoidable. Some may insist on calling a crash an accident if there was no obvious human error. Contributing factors such as a slippery road surface or a vehicle system failure might make the crash appear accidental, but advocates for the term crash point to the avoidable aspects. In other words, crashes are not accidents if the people involved could have used safer behaviors in response to conditions.

What we Call Things Matters

The final argument for the term crash is the most compelling to me as a behavioral and cognitive psychologist. It is about changing attitudes through word usage. The traffic safety practice has many issues where naming conventions matter. Observations from the sciences of human factors, cognition, and social psychology are relevant. Considering early implementations of autonomous vehicle technology is instructive. In several documented incidents, the drivers were operating in the so-called self-driving mode under circumstances where its use was specifically warned against by the manufacturer. A big part of the problem is that people fail to read and understand their vehicle owner's manual, but there is also a serious concern that what the systems are called is at least partly to blame for an overreliance on the technology. In short, owners believed the car could truly operate autonomously in all situations because they believed the labels for the assistance technologies. What we call something obviously matters.

The word crash means something different from the word accident. Crash does not call to mind something unavoidable. When people hear the word crash they are apt to think of a serious event or consequential system failure. It evokes an image of a serious situation caused by a problem in how a thing was designed, constructed, or used. It even sounds like what it is in a nearly perfect example of onomatopoeia—although advocates would caution that events that do not make that noise are still counted as crashes. Conversely, if we use accident, that could be construed as if no one is at fault and the events happened for reasons beyond anyone's ability to control or predict. Industrial safety professionals have argued that the word accident should not apply to any situation involving interactions of people and systems—that its use is off target in industrial settings as much as it is for traffic safety. Some go further and argue that we live in a safety culture (specifically a traffic safety culture is meant to imply that whether we know it or not, and even if the culture is one of dangerous behavior, a safety culture exists and we all share the norms of that culture). Part of having such a culture is agreeing on the terms and definitions we will use—again, we generally agree on these things even if our safety culture is one that yields poor outcomes. By these views, the issue nearly settled—accident is too narrow and specific to encompass all of the events we are describing.

An International Understanding

I live and work in the United States. I have many international colleagues in traffic safety and I took this assignment seriously enough to find out if a similar word choice discussion has occurred in their countries. The International Standards Organization's English language versions of the relevant standards (e.g., ISO 39001 on road traffic safety management) use crash and accident interchangeably. Based solely on my own language skills, I looked first at countries where English is the dominant language. In Canada, the traffic safety publication by Transport Canada uses crash exclusively. TIRE, a research group based in Canada but with an international reach, has clearly advocated in favor of crash as the preferred term. One UK-based journal, the *BMJ* has banned the word accident. In Australia the discussion has taken place along the same lines and the safety practitioners have settled on crash. A scan of newspaper articles from these countries shows the same variability as seen in the United States, with crash, accident, and various other terms used synonymously.

For the remainder of the world, however, this discussion of terminology appears not to have taken place and it does not appear that there is a strong movement away from the equivalent term for accident. Indeed, I am informed by some colleagues outside the English-speaking parts of the world that this discussion seems quaint and baffling from their perspective. Even in places with strong safety cultures—as in Northern Europe where the focus on safety has a long history—the debate over terminology is reportedly a nonissue. In other countries there appears to be a firm commitment to the idea that crashes are accidental in nature—that nobody planned to crash and thus the event itself was an accident. This latter viewpoint, of course, dispenses with the secondary understanding (advocated for in English-speaking nations) that accident implies a degree of unpreventability. As noted earlier, this is the source of the concern for practitioners making the case for crash. But, as discussed earlier, even in the United States and Canada, preventability argument is not universally accepted. It is a weakness of this article that I do not possess the language skills needed to truly parse the discussions of terminology in multiple languages around the globe. I have relied on a set of busy international colleagues whose English is better than my skills in any of their country's native languages. I make no claims to having provided proof that similar discussions are not happening or that the non-US-English cognates for accident clearly mean only that an event was unplanned. Nor do I claim that other countries are behind the United States in their concern over traffic safety. Popular accounts of street protests in multiple countries over lax traffic safety laws or enforcement show that people do care deeply about their ability to travel safely.

Why Not Wreck or Collision?

First, let's look at collision as a substitute. It was popular for a time as it avoids the connotation of things being purely accidental. A problem arises for safety practitioners because collisions are specific types of crashes—they involve the colliding of a motor vehicle with something or someone else: another car, a barrier, a pedestrian, or a bicyclist. There are crashes that do not involve collisions such as untripped rollovers. So, collision is too narrow a term. Wreck is also not a good substitute for crash. One obvious problem is that wreck conjures up images of (perhaps even ruinous) damage to the vehicles. If a driver got in a wreck, it typically means that their vehicle sustained serious damage. Therefore, wreck is not an appropriate substitute if there was no vehicle damage. One does not get in a wreck at low speeds with a pedestrian, even if the pedestrian is injured. That is definitely a crash.

What does the Science Say?

As of the date I wrote this, there are no studies that provide direct evidence of safer behavior among those who adopt the term crash versus accident. There are studies that demonstrate an impact of word choice on things such as perceived risk and blame ([Fausey and Boroditsky, 2010](#)). Not surprisingly, passive wording convinces people that there is no blame to be apportioned, while active wording does the opposite. In the scientific literature for traffic safety there is no clear consensus. Authors studying crashes often even use both terms interchangeably. One of the top journals in the field has the word accident in its name. All of that may change in the

future. I expect that a study of word choice and perceived risk would show a clear difference between the words crash and accident, but we do not know that yet. It appears likely that journals publishing scientific articles on the topic will come to favor crash over accident in their titles and in their style guidance for authors. It is a slow process, but one that is moving in an obvious direction.

Intentional Acts Should Never be Called Accidents

Traffic safety analyses in the United States and many other countries generally exclude events involving deliberate use of a vehicle to harm oneself or others or to cause damage. ANSI D16 explicitly excludes obviously intentional events, as does the guidance from NHTSA for the Model Minimum Uniform Crash Criteria (MMUCC) and Fatality Analysis Reporting System (FARS). These are not accidents, but they are also not part of a typical crash analysis. A quick search of media coverage of intentional events shows a disturbingly frequent use of the word accident for what were obviously deliberate acts. A person using their car to purposefully run over pedestrians was not in an accident. A person committing suicide by driving off a cliff did not cause an accident. From a traffic safety perspective, analysts drop these intentionally harmful events from the databases we use for analyses.

Exclusion criteria are, however, quite narrowly defined. From a safety analysis perspective, we know some intentional choices lead to crashes or increase their severity, yet we still include them in our analyses. Logically, many contributing factors could be called intentional even if the resulting harm was not intended. A drunk driver intended to get behind the wheel while impaired. They may not have consciously decided to get into a crash and cause injury or damage, but they chose a dangerous behavior that vastly increased their risk of causing a crash. The same is true of a distracted driver, or one who drives aggressively. People decide not to use protective devices (seat belts, child safety seats, motorcycle helmets, etc.) vastly increasing risk of serious injury or death if they are involved in a crash. It is difficult to call the consequences of such deliberate choices accidental.

Accident is also a strategic word choice used by defense lawyers hoping to help their clients avoid criminal convictions or civil liability. It is not a word choice most of us would consciously agree with when we know that the involved driver actively chose to behave in an unsafe manner. The real debate over crash versus accident can safely exclude a portion of the events—those that have a measure of intent. The real question is how much intent and what intentions are required in order to avoid use of the word accident. Indeed, safety advocates argue that there really are no accidents by this criterion. People may not have set out to crash, or to injure themselves or others, or cause damage, but their choices that raised the risk of those outcomes were deliberate. Was that unplanned or simply unthinking?

Why Bother?

The grassroots advocacy organizations WeSaveLives, Transportation Alternatives, and Families for Safe Streets make the case most eloquently based on the personal experiences of their founders and members. Their loved ones did not die accidentally—they died in a car crash because of multiple reasons, predominantly human errors as well as (more rarely) unsafe conditions on the roadway or problems with the vehicle. That is truly the situation for nearly all the fatalities and injuries on our roadways—a person chose to act in a risky manner and someone was hurt or killed. If that applies to more than 90% of these incidents, calling them accidents is a disservice to the victims and their families. This point of view is simultaneously emotional and factual—a powerful combination. These safety advocacy groups and their traffic safety allies are working with a purpose. They want the laws changed to recognize the role of human choices and other recordable factors. They want the media to use a word that does not support deliberate miscasting of the events or promote fatalist attitudes about the deaths and injuries on our roadways. Crash does that in a way that accident does not.

Some still argue that accident can carry this load. Clearly, for most of the world, the equivalent word for accident works just fine. They say we can study the causes of accidents and try to avoid them in the future. The problem is that, for some, accident has two popular definitions and one of those absolves people or entities of blame. That's why the auto industry began promoting its use more than 100 years ago. The word mattered then, and it played a role in conditioning us to accept the fault-free inevitability of what are truly preventable events. While we are more savvy now and know that harmful incidents are signs of a solvable problem, there is still the lingering idea that causal attribution is too elusive or does not matter so long as we can mitigate the problem.

Safety advocates, though, have a wealth of experience to draw on. We know that grassroots efforts can drive change. We have seen it in drunk driving and seat-belt use, to cite two well-studied examples. We also know that laws can change through public pressure. Already some states (e.g., Arizona) are changing their traffic laws to eliminate the word accident. This is why the safety advocates bother asking for a word change; by making that change, they know we are more likely to affect a change in attitude that drives behavior. This is the safety culture approach—a shared set of values and beliefs that include, in this case, that crashes are almost always preventable. We have an opportunity to use the power of social norming, as we did for drunk driving and seat-belt use, to signal through our words that we do not accept the antiquated view that injuries and deaths on our roads are accidental. Truly, they are not.

Acknowledgments

I would like to thank my colleagues Pamela Shadel Fischer, Kathleen Haney, Tim Kerns, Jeff Larason, and John McDonough for helping me by sharing their time, resources, and expertise. I also thank Per Garder for insightful comments and assistance.

Introduction

The influences of gender and age on traffic crash risk are well documented in road safety research. In spite of cultural and geographic differences between different regions of the world, the degree to which males are overrepresented in fatal crashes is uncannily similar across many different countries (around 75% traffic fatalities are male in most of the countries). Such trends are often attributed in part to the different driving behaviors of males and females, though exposure is a factor as well. Internationally, males are typically more mobile than females—as drivers, passengers, pedestrians, and cyclists—hence, more commonly exposed to traffic crash potentials. Wherever possible, however, analysis has normalized crash involvement of the genders—either by comparing rates within certain populations (e.g., within the populations of licensed drivers) or by normalizing for relative mobility by looking at miles or kilometers traveled. In all cases, the conclusion remains strong that males are more at risk of fatal crash injuries than are females.

Age as a unit of analysis is similarly noteworthy, as young people are more likely to die in road crashes across the world than middle-aged road users, while the elderly are physically frailer and so are more susceptible to death in the event of a crash than younger people. Age cannot be entirely separated from gender as age and gender combinations produce distinct patterns of crash likelihood. Young men, for example, are at heightened risk when compared with young women, but in contrast elderly females are overrepresented in injury statistics when compared with elderly males. The research confirms that gender and age are strong influences on crash risk, only marginally influenced by social norms or geography.

Gender

A significant trend in male overrepresentation in road crashes is evident from various traffic data collected from across the world. For example, in the United States, data from the National Highway Traffic Safety Administration (NHTSA) for 2015 confirmed that the crash involvement rate per 100,000 licensed drivers was 1.605 for males, and 1.274 for female drivers. For all reported crash types, licensed male drivers were 26% more likely to be involved in a crash than licensed female drivers. Even more critically, male deaths represented 74.4% of all traffic deaths in 2015 (35,297 male deaths compared with 12,172 female deaths in 2015), yet the miles driven by male drivers constituted only 62% of total miles driven. Male drivers are clearly overrepresented in fatal crashes when their miles traveled are considered.

In the United Kingdom, these percentages are similar: the number of males reported killed in traffic crashes for 2017 was 1345 versus 474 female deaths, with 74% male deaths as compared to 26% female deaths. Again, male miles driven in the United Kingdom are not comparable with their death rates—only 64% of miles driven in the United Kingdom are driven by males. Male deaths are once again higher than would be expected based on exposure levels alone.

Exposure is a combination of the time people spends on the road, mileage covered, and traffic conditions they are exposed to (Elander et al., 1993). The higher the exposure to traffic crash potential, the higher the individual's likelihood of being involved in a crash. All things being equal, we would assume that all road users with identical exposure rates would be equally represented in

Figure 1 Annual distribution of fatalities by gender in the EU, 2006–15. Source: European Road Safety Observatory (2019).

crashes, but in the gender dimension, this is not the case, as is evident in the United States and United Kingdom examples. They are not unique.

In Europe, 76.2% of the EU region's fatal crashes involved males in 2015. Again, this exceeded the difference in miles driven by male drivers. Research in Spain, for example, indicates that the average number of kilometers traveled per day by males is only 22% higher than that of females (Ayuso et al., 2016).

Gender percentages of traffic fatalities from 2006 to 2015 show how strikingly consistent the ratio of male to female deaths has been over that decade (Fig. 1).

These patterns are similar for most regions of the world (this analysis excludes countries, such as Saudi Arabia and Iran where drivers are almost exclusively male).

Much of the analysis worldwide focuses on males as drivers, that is, when they are in control of driving decisions. However, as pedestrians and passengers, males, again are more at risk of being killed on the road than females, indicating that for every mode of transport, males are more likely to die in traffic crashes than females. In the United Kingdom, for example, female pedestrians are responsible for slightly over half pedestrian trips taken each year (52%) but 57% of pedestrians killed are males. Similarly, as shown in Fig. 2, across Europe male pedestrian deaths, and male passenger deaths, outnumber those of females.

Fatal crashes typically are the most extreme of crash types; that is, where injuries are severe enough to cause death. In slight and non-injury crashes, this pattern does not always hold true, which has interesting implications for behavioral research. For example, a Spanish study in 2017 found that male pedestrians were more likely to be involved in slight injury crashes only in the age groups of 4–13 years, and 25–44 years. In fact, from the age of 54 years and higher, females were more likely than males to be slightly injured as pedestrians in crashes.

The academic response to male overrepresentation in crashes and fatal crashes in particular has been to develop research into road user behavior and gender attributes. Behaviors exhibited by both genders, such as risk-taking, aggression, and rule violation are commonly analyzed under gender research studies.

Figure 2 Road fatalities by gender and road user—Europe 2015. Source: European Road Safety Observatory, 2017. Annual Accident Report 2017. Available from: https://ec.europa.eu/transport/road_safety/sites/roadsafety/files/pdf/statistics/dacota/asr2017.pdf.

Risk-Taking

Research has showed very clearly that males have a far higher tolerance for risk in driving and in pedestrian activity, than females (DeJoy, 1992; Clarke et al., 2010). This means that they show greater inclination to drive at higher speeds (Stradling et al., 2003) and also under more difficult driving conditions, such as poor weather, or at night (Bener and Crundall, 2008), than females. In studies of pedestrian crossing behavior, males have been found to cross with smaller gap acceptance levels than females (Ishaque and Noland, 2008). Many of these are unconscious decisions. When appetite for risk is an embedded factor in an individual's personality, their propensity for intentional risky driving behavior increases. Risky behavior includes speeding for the thrill of it; following the vehicle ahead too closely, violating traffic rules, not using seatbelts, using mobile phones while driving; text messaging driving during high-risk night-time hours, and driving older vehicles. Of course risky personality traits can be found in females as well, but these are significantly less common, with anthropologists arguing that risk-taking behavior in males has been a necessary element of human evolution, with risk-taking among males typically factors in exploration and competitiveness among our early human ancestors.

Compliance With Traffic Legislation

Both age and gender have been found to be contributory factors to the likelihood of traffic violation. The likelihood of traffic violations is reported to be highest for males, young drivers and with increasing levels of mobility (González-Iglesias et al., 2012; Oppenheim et al., 2016).

Age

Until now gender has been discussed as if it affects crash risk consistently, irrespective of age. This is not, in fact, the case. Gender and age are interlinked elements in crash causation—young road users demonstrate significantly more distinct gender imbalances in crash involvement than do middle aged or elderly road users. Three European countries, for example, the Netherlands, Sweden, and the United Kingdom, reported that young males (under 25 years) have a fatal crash rate per million kilometers driven that is 3 times higher than that of females of the same age.

Common patterns of crash involvement can be identified in even a cursory examination of the age of traffic victims. In the United States, for example, crash rates per 100 million miles driven show clear differences in crash risk for all crashes, injury crashes, and fatal crashes (Table 1). Gender differences in crash risk appear to be most exaggerated among young road users—a phenomenon seen worldwide. This suggests that age is a compounding factor in road behavior and hence in crash risk.

Following the same logic as with gender, exposure, and road user behavior are the primary contributory factors in age-related crashes, with overrepresentation of certain ages again evident.

Different countries and regions divide age into comparative cohorts in different ways. Wherever possible ages are recorded in 5-yearly increments and this gives the most useful picture of crash involvement for each stage. However, such reporting can be onerous and groups with similar crash tendencies are often grouped together. In this categorization, and at the most basic level, there are four broad categories: children (typically defined as being under the age of 18 years though in countries where driving is permitted from 16 years of age this group tends to be < 16 years); young people/youth (18–24); middle aged (25–49 years), and elderly (50–64 years and above). Of course these groupings are themselves crude and distinctions can be found within them. For example, under the category of young people, novice drivers tend to be identified as the youngest among the group—those who are starting to drive, that is, typically between 16 and 21 years of old, whose risks as drivers are particularly notable. Among elderly drivers too, behavior and vulnerability change dramatically with age, with the older road users both more prone to error and more likely to die in the event of a crash than elderly drivers at the younger end of the range.

Table 1 Crashes and crash severity by age, United States rates per 100 million

Age	All crashes	Injury crashes	Fatal crashes
16–17	1432	361	3.75
18–19	730	197	2.47
20–24	572	157	2.15
25–29	526	150	1.99
30–39	328	92	1.2
40–49	314	90	1.12
50–59	315	88	1.25
60–69	241	67	1.04
70–79	301	86	1.79
80+	432	131	3.85

Children

The 2018 WHO annual status report on road safety confirms the significance of traffic injuries to young people when it reports that traffic injuries remain the leading cause of death for children and young adults aged 5–29 years.

By virtue of their small size and relative weakness, children are physically more fragile than adults and an impact that may simply injure an adult has far more potential to cause serious injury or death in children. They are, as a result of their anatomy alone, more vulnerable to serious injury than adults.

They are also more vulnerable to making errors as road users than adults, and largely dependent on adults to keep them safe. The child road user (up to the age of around 12) has physiological limitations and is exposed to higher risk within the traffic environment when compared to adults. While even young children have fairly well developed peripheral vision, the complex perceptions required to comprehend traffic risk emerge over time. In particular, children's ability to judge speed and distance of vehicles is dependent on their acquiring sufficient experience to build up a useful set of comparisons. They do not yet have the experience to be able to accurately determine which direction a sound may be coming from. To be safe on the roads, children must have advanced visual search skills, which allow them to determine very quickly what elements of the road system are dangerous and which are not. Research suggests that skills of this nature really come together in children from the age of 7 years—until then, children are unable to process all the information needed to be taken care of while crossing a road or walking along a road. Also, because they do not drive, they cannot fully anticipate what a driver's intentions might be at a junction or crossing point, and in fact this is a problem facing adults who may not be able to drive as well.

As passengers in vehicles, children are entirely dependent on adults to both navigate their vehicles safely, and to secure them in age appropriate child restraints which will give them the best possible protection in the event of a crash. Young children have specific physiological limitations that render them particularly vulnerable to serious injury in a collision. The skulls of infants are extremely malleable until around 24 months. Even low levels of force on the skulls of children of this age can result in significant deformation and brain injury. The infant/child ribcage is similarly flexible and the abdominal organs are poorly protected. Not surprisingly, given the physical limitations of children, child restraint systems have proven to be significantly better at reducing fatality risk to children than conventional seatbelts (Elliott et al., 2006).

Although airbags reduce fatal crash injuries among adult drivers and passengers, this safety technology can increase mortality risk among children, and it is increasingly uncommon for infant or child car seats to be used in the front passenger seat of a car. In countries where it is still considered acceptable for child car seats to be placed on the front passenger seat, it is always recommended that car seats be placed in a rear-facing position to prevent injury should an airbag be inflated.

Youth

As young people emerge from childhood, their exposure to potential crashes generally increases as their independent mobility grows. At this age, the young adult may have fully formed physiologies, with eyesight, hearing, and reaction times as good as they will ever be, but they are hindered by inexperience in traffic and also the personality and gender-based propensities for risk that emerge in adolescence—sensation seeking, peer pressure, and bravado are common features among young people that make them more vulnerable to error. Young (novice) drivers contribute to a sizable proportion of fatal road crashes (Oxley et al., 2014). Gender plays a key role again in this cohort, with young male drivers demonstrating a notably higher crash risk—and fatal crash risk—than female novice drivers (Whissell and Bigelow, 2003; Ivers, 2009).

Crashes involving young drivers are more likely to be single vehicle crashes, and to be speed related, than among any other age category. Alcohol use is also highest among crashes by young drivers (and lowest among elderly drivers).

The vast majority of novice drivers are still developing emotionally, psychologically, physiologically, and socially. A large body of research explains how these developmental features of young people contribute to elevated crash risk. These include personality-based factors, such as aggression, exhibitionism, recklessness, and a lower respect for authoritarian rules and regulations (hence a heightened likelihood to break traffic rules) than more mature drivers. Research has repeatedly found that young male drivers are more prone to engage in risky driving behavior, such as speeding and driving after consuming alcohol. This finding is consistent across all countries and all cultures. In addition, levels of deviant behavior or rule breaking are also much higher among younger males than among any other group of road users.

The presence of passengers has been shown to have a direct bearing on the likelihood of teenage drivers engaging in explicitly risky behaviors. In the United States, young teenage drivers are 2.5 times more likely to engage in one or more potentially risky behaviors while driving if a teenage peer were present, compared to when driving alone. The same research confirms that when driving with more than one peer, the likelihood of engaging in risky driving behaviors, increases by up to 300%.

Cognitive research studies confirm that new drivers do not yet have fully formed skills in hazard recognition. Drivers move through a complex road environment and novice drivers must learn to scan, detect, and react appropriately to hazardous road environments. As with young children gradually learning through experience as to how to safely navigate the road traffic environments, novice drivers acquire the cognitive skills necessary for safe driving over time and with growing levels of experience. Studies of first crash timing of young drivers show that there is a sharp decline in the crash risk per kilometer driven during the first few months after licensing which indicates that the months after the licensure are most critical in terms of completing their skill development (Mayhew et al., 2003). It is during this time, too, that the motor skills associated with maneuvering the vehicle are also fine-tuned—novice drivers get more technically competent over these critical months.

Middle-Aged Road Users

Almost no exceptional risk factors exist for this group. The earlier desires for sensation-seeking, peer pressure, and exhibitionism are generally under control among middle-aged road users, and the responsibilities that come with having careers and raising families tend to curb the natural risk-seeking behavior even among males. Within this cohort, males are still slightly more likely to be killed in a crash than females, but the risks are far more balanced.

Elderly Road Users

Since 1990, the global life expectancy of humans has increased by approximately 6 years. It is therefore safe to assume that the proportion of elderly people as road users also increases over time. In fact, a significant increase in the proportion of road traffic deaths in the age group older than 70 years has already become noticeable in high-income countries. The difference is most likely related to longevity in these countries, combined with the greater risk posed by reduced mobility and increased frailty.

Despite the vitality of many older persons, gradual changes in the ability to perform complex tasks, such as driving and avoiding accidents becoming evident with increasing age. Biologically, the body loses the ability to renew itself, the bodily functions weaken and vital organs become less robust. There is a decline in sensory process, perception, motor skills, and problem solving skills. Crashes involving older drivers often occur in more demanding driving environments, such as at intersections, or where important information from the road can be misread or misinterpreted (e.g., judging other vehicles speeds, or stopping distances). For the elderly, their heightened risk of being involved in a crash comes from the combined failure of initial judgment (as a result of sensory loss with age), and the failure to accommodate or modify behavior to avoid a developing incident.

The elderly are physically frailer than younger adults; their injuries will be more severe given an identical collision impact involving a younger person. The fatality rate is approximately 3 times higher for a 75-year-old motor vehicle occupant than for an 18-year-old. They are more likely to sustain fractures to all body parts in a crash, recovery time is much longer and the likelihood of long-term disability is high.

While elderly females are involved in more crashes than males (of all severity), this is largely a function of the fact that there are simply more elderly females than males in traffic. Almost all countries experience higher survivability rates of women than males among the elderly. In the United States, for example, in 1998 the number of women per 100 men was 123 at ages 65–74; 151 at ages 75–84, and 241 at ages 85 and older. More elderly women road users are involved in crashes simply there are more of them overall. However, when only drivers are considered, males remain overrepresented in crashes when compared with females (normalized against numbers of drivers of the same gender). This is true for all injury crashes as well as for fatal crashes.

The gross number of crashes involving elderly drivers is lower than might be expected. Reasons for this are generally attributed to the fact that the elderly tend to actively manage their driving risk—driving at times when there is less traffic on the roads, avoiding high volume intersections, and high-speed roads, for example, or avoiding nighttime and long-distance driving. At some point in their lives, elderly drivers choose to give up driving altogether and become more dependent on other drivers, public transport, and walking. They thus regulate their exposure to risk more actively than younger drivers.

The occurrence of pedestrian fatalities is the highest for ages older than 55 years and younger than 12 years in all European countries. A report the European Union showed that pedestrians aged 65 years and older, though representing only 15% of the total population, accounted for 45% of all pedestrian fatalities. Similar results were found in a study from Sri Lanka where 43% of pedestrian fatalities occurred in the age group of 65 years or older. The Monash University Accident Research Centre has found that the number of cycling fatalities in this age group can increase up to 70%.

Implications for Road Safety Going Forward

Risky behavior associated with males, and young people, constitute some of the biggest challenges to improving road safety across the world. Changing road user's chosen behavior relies on effective education campaigns, but traffic law enforcement could arguably be the better option for behavior that is intentionally willful and risky. Improving young driver's skills at hazard perception, and children's ability to recognize the location of hazards and to prioritize them, can be improved with age-appropriate training—much work is being done on hazard recognition as part of driver training, for example. Safety challenges associated with young drivers can be addressed in part through better training and graduated licensing programs, which are being utilized to good effect in some parts of the world.

The fact that most drivers of fleet vehicles, heavy goods vehicles, and public transport vehicles are male, means that the drivers of these vast fleets of vehicles are more at risk simply as a consequence of their gender. Gender sensitivities mean that few are likely to suggest that males should be prohibited from these professions, but there is also a tendency to avoid suggesting that special remedial programs for professional male drivers have a role to play. Given that scientific evidence clearly shows heightened crash risk among male road users, this sensitivity is undoubtedly misplaced, and going forward it seems essential for road safety initiatives to derive and prioritize gender—and age-specific programs for behavioral adaptation.

Introduction

Aggressive driving includes any behavior by a motorist intended to physically, emotionally, or psychologically harm another road user in the roadway environment ([Hennessy and Wiesenthal, 2002](#)). Such behavior occurs worldwide and increases the likelihood and severity of motor vehicle collisions ([Galovski et al., 2006](#); [Paleti et al., 2010](#); [Sârbescu et al., 2014](#); [Stephens and Fitzharris, 2017](#); [Stephens and Sullman, 2015](#); [Sullman et al., 2017](#)). Considerable research has been devoted to classifying types of aggressive driving behavior and identifying factors that increase and decrease the risk of its occurrence.

Defining Aggressive Driving

The driver behavior literature makes mention of multiple related terms, including aggressive driving, risky driving, road rage, retaliatory aggression, hostile aggression, dangerous driving, and instrumental aggression, among others ([Haje and Symbaluk, 2014](#); [Suhr and Dula, 2017](#); [Suhr and Nesbit, 2013](#); [Zhang et al., 2017](#)). These terms are not synonymous, necessitating careful consideration for appropriate term usage. For example, the act of speeding in order to tailgate and intimidate another motorist constitutes both risky and aggressive driving. Speeding to get to a destination sooner is risky driving, but not aggressive driving. All aggressive driving can be considered risky driving, but not all risky driving can be considered aggressive. Similarly, the term road rage is often used to describe severe behavior such as deliberately damaging another vehicle or engaging in a physical altercation with another road user. All acts of road rage can be considered aggressive driving, but not all acts of aggressive driving can be considered road rage.

Theoretical Perspectives of Aggressive Driving

Over the years, researchers have proposed several psychological theories to attempt to explain aggressive driving. The theory of planned behavior posits that attitudes, subjective norms, and perceived behavioral control interact with each other and contribute to

a person's intentions, which in turn contribute to a person's behavior (Ajzen, 1991). The frustration-aggression hypothesis posits that obstructing achievement of one's goals leads to frustration, which increases risk of subsequent aggression (Dollard et al., 1939). Both theories involve the interaction of situational events, cognitions, and emotions, influencing aggressive behavior (Efrat and Shoham, 2013; Shinar, 1998). The General Aggression Model incorporates and builds on both the theory of planned behavior and the frustration-aggression hypothesis (Anderson and Bushman, 2002). The General Aggression Model proposes that person-related factors (e.g., gender) and situation- or environment-related factors (e.g., rude gesture or heat) influence a person's emotions, cognitions, and physiological arousal, which in turn influence the decision-making process, potentially resulting in aggressive behavior. Furthermore, prior experienced events and reactions can cycle back and influence how subsequent events are experienced (Anderson and Bushman, 2002). The General Aggression Model provides a comprehensive theoretical framework outlining the emergence of aggressive driving behavior. The contributing factors subsequently discussed in this article can be placed within the framework of the General Aggression Model.

Person-Related Contributors to Aggressive Driving

Factors identified as contributors to aggressive driving generally fall into two categories: person related and situation related. Person-related factors, which represent the majority of contributing factors identified to date, are specific to the driver.

Demographic Factors

Demographic factors (e.g., age, gender, education level) are the most stable characteristics of a person; they do not change from situation to situation. Compared to females, males are more likely to engage in aggressive driving, although this difference is most consistent and most pronounced when more severe forms of aggressive driving (e.g., road rage) are examined (Hennessy et al., 2004). Younger, compared to older individuals are more likely to drive aggressively (Wickens, Mann et al., 2011). Accordingly, young male drivers tend to engage in more aggressive driving than other demographic groups (Arnett, 2002; González-Iglesias et al., 2012; Roberts and Indemaur, 2005; Wickens, Mann et al., 2012).

Personality Factors

Personality traits are a combination of a person's thoughts, feelings, and behavior. Traits influence how we respond cognitively, emotionally and behaviorally to everyday events and situations. As they are believed to be relatively stable over time, traits have been the focus of much of the aggressive driving literature. Not surprisingly, individuals with higher levels of trait aggression, the tendency to exhibit verbal or physical aggression across situations, are more inclined to engage in aggressive driving (Deffenbacher et al., 2003). Similarly, trait anger is the tendency to frequently experience anger, with varying intensity, across situations. Individuals who possess high trait anger are more prone to drive aggressively (Bogdan et al., 2016; Herrero-Fernández, 2013; Stephens and Groeger, 2009). Drivers who are more prone to experience stress behind the wheel due to time constraints, traffic congestion, or poor weather conditions are also more prone to drive aggressively (Hennessy and Wiesenthal, 1999). Narcissistic individuals are generally selfish, self-absorbed, entitled, and possess fragile self-esteem. It is believed that narcissists engage in more aggressive driving because it serves as a defense mechanism against threats toward their self-esteem or entitlement (Lustman et al., 2010). Drivers who possess greater impulsivity are more likely to behave with little or no consideration of the consequences. Impulsive drivers are more likely to retaliate against a perceived offense by another motorist, leading to the escalation of roadway aggression (Dahlen et al., 2005). Other personality traits that have been shown to increase aggressive driving include neuroticism, sensation seeking, ego defensiveness, extraversion, emotional instability, hypermasculinity, and Type-A personality (Bone and Mowen, 2006; Dahlen et al., 2005; Dahlen and White, 2006; Matthews et al., 1991; Miles and Johnson, 2003; Neighbors et al., 2002; Sümer et al., 2005). Conversely, other personality traits have been shown to reduce the risk of aggressive driving. Conscientious individuals tend to be careful and self-disciplined, which may result in driving behavior that falls within the confines of social norms and the law (Chraif et al., 2015; Jovanović et al., 2011). Agreeableness is characterized by qualities of kindness and consideration. Agreeable drivers may be more likely to be accepting of other driver's poor behavior, resulting in a reduced risk of retaliation (Chraif et al., 2015; Jovanović et al., 2011). Similarly, trait forgiveness, which is characterized by a tendency to consciously release feelings of resentment and retribution toward a wrong doer, influences aggressive driving. Drivers high in trait forgiveness are able to release their hostile and retaliatory feelings toward other motorists, reducing the likelihood of an aggressive behavioral response (Kováčsová et al., 2014; Moore and Dahlen, 2008).

Cognitive Factors

Cognition includes attributions, perceptions, and ruminations; essentially the mental process through which all stimuli from the world around us are processed. Cognitive factors influence how a person experiences, feels, and reacts to events and situations. In the driving environment, our cognition shapes the way we assess interactions with other motorists and plays a significant role in identifying and selecting our response to those roadway events.

Attributions are the means by which individuals explain the causes of behavior and events. Research has shown that the more a behavior is perceived to be intentional and caused by a specific person, the more that person is deemed to be responsible for his or her behavior (Mikula, 2003). In the driving environment, motorists are more likely to react aggressively if they perceive themselves to be victims of another motorists' negative behavior and that behavior is deemed to be intentional; the offending driver will be judged as more responsible for the negative outcome (Wickens, Wiesensthal et al., 2011). Consider a situation in which you are cut-off by another vehicle. If you believe the other motorist had control over the behavior (i.e., turning the steering wheel) and intended to cut-off your vehicle, you will attribute more responsibility to that motorist and be more likely to respond aggressively. If, however, you believe the other motorist had control over the behavior but intended only to avoid a collision with an animal on the road, you will attribute less responsibility and be less likely to respond aggressively.

Cognitive bias, an error of information processing, can also play a role in aggressive driving (Wickens et al., 2014). When interpreting a negative event caused by another motorist, we are more likely to overestimate internal factors (e.g., driver's age) than external factors (e.g., road conditions). This is known as the actor-observer bias (Jones and Nisbett, 1971). Overestimating internal factors will lead to increased attributions of responsibility (Britt and Garrity, 2006; Hennessy et al., 2005; Lennon et al., 2011). As mentioned earlier, attributing responsibility to an offending driver increases the likelihood of aggressive responses. Another cognitive bias, the illusion of control, leads motorists to overestimate their level of control over an outcome. Illusion of control is defined as the tendency to view chances for success as higher than the probability warrants (Langer, 1975). Drivers with an increased level of illusion of control will attribute chance outcomes (e.g., avoiding a collision when driving aggressively) to their own skill (Stephens and Ohtsuka, 2014). This overconfidence regarding a collision or negative consequence of reacting aggressively is what leads to increased aggressive behavior.

Rumination involves repetitive and uncontrollable thoughts about negative internal or external experiences. Increased rumination has been found to contribute to increased feelings of anger, physiological arousal, and aggressive driving (Suhr, 2016; Suhr and Dula, 2017; Suhr and Nesbit, 2013). Furthermore, increased rumination not only leads to increased aggression toward the provocateur, but it has also been shown to increase aggression toward third-party individuals (Bushman et al., 2005; Pedersen et al., 2011). For example, a motorist who ruminates about being dangerously cut-off will be more likely to react aggressively toward other motorists who were not involved in the original transgression.

Attitudes and Social Norms

Attitudes are evaluations of a target, which may be a person, place, thing, or event (Ajzen, 2005). Attitudes can be positive or negative. Positive or permissive attitudes toward aggressive driving increase an individual's likelihood of behaving aggressively while driving, whereas negative attitudes toward aggressive driving have the opposite effect. Negative attitudes toward bicyclists have also been associated with positive attitudes toward aggressive driving and engagement in aggressive driving targeting bicyclists (Fruhen and Flin, 2015). Attitudes can apply to very specific circumstances; a driver may have permissive attitudes toward aggressive driving that target other motorists but not bicyclists, or toward drivers of a particular demographic (e.g., young/old, male/female). Stereotypes held about the driving skill or driving style of certain motorists may inform these attitudes (Davies and Patel, 2005; Lawrence and Richardson, 2005).

Social norms are a broad range of behavior considered to be acceptable by society. An individual's perception of social norms or acceptable behavior can influence their subsequent behavior. Motorists who perceive aggressive behavior toward bicyclists to be socially acceptable are more likely to behave accordingly (Fruhen and Flin, 2015).

Mental Health Factors

Mental health affects our ability to cope with stress, interact with others, and make decisions, all of which are essential to safely navigating the roadway environment. Mental health issues, therefore, can impair roadway safety, including via increased risk of driver aggression. Intermittent explosive disorder, for example, is characterized by impulsive expressions of extreme anger that are out of proportion to the anger-provoking stimulus (American Psychiatric Association, 2013). Compared to nonaggressive drivers, aggressive drivers have been found to be more likely to meet the diagnostic criteria for intermittent explosive disorder (Galovski et al., 2006). Attention deficit hyperactivity disorder (ADHD) is also characterized by impulsivity, as well as inattention and hyperactivity. Individuals with ADHD are more likely to report driver anger and aggression compared to individuals without ADHD (Barkley and Cox, 2007; Richards et al., 2006). Conduct disorder is characterized by extreme externalizing behavior and a prolonged pattern of antisocial behavior that violates the rights of others or age-appropriate societal norms or rules (American Psychiatric Association, 2013). Research has found that symptoms of conduct disorder are predictive of aggressive driving behavior and collision risk (Wickens et al., 2015, 2019). Additional research has found evidence that personality disorders (e.g., antisocial personality disorder, borderline personality disorder) significantly increase the odds of perpetrated driver aggression (Galovski et al., 2002), and there is some evidence to suggest that other psychological disorders (e.g., major depressive disorder) may as well (Butters et al., 2006). Likewise, a history of traumatic brain injury (e.g., concussive injury) has been associated with an increased likelihood of threatening physical harm against other motorists or other vehicles and with increased risk of collision involvement (Ilie et al., 2015).

Mental health is also influenced by use of alcohol and recreational drugs such as cannabis, cocaine, and ecstasy/MDMA. Each of these substances has pharmacological effects, which may impact one's mood and inhibition and may increase one's risk of engaging

in driver aggression (Benavidez et al., 2013; Butters et al., 2006; Fierro et al., 2011; Richer and Bergeron, 2009; Wickens, Mann et al., 2011). It may also be that individuals who engage in driver aggression are characterized by demographic or personality traits that predispose them to risk of problematic alcohol or drug use (Benavidez et al., 2013; Mann et al., 2004). There is also evidence to suggest that users of more dangerous illicit substances (e.g., cocaine, ecstasy/MDMA, heroin) are at risk of perpetrating *serious* driver aggression or road rage (i.e., threatening or attempting to damage another vehicle or harm another driver) (Benavidez et al., 2013; Butters et al., 2006).

Emotional Factors

Emotion is a complex mental state resulting in physical and physiological changes that influence behavior. Anger is defined as an emotional state marked by subjective feelings varying in intensity from mild annoyance or irritation to intense fury and rage (Spielberger et al., 1985). Within the aggressive driving literature, anger has been researched more than any other factor, both as an independent contributor and as a mediator or moderator of other relevant factors. Anger may be particularly predictive of driver aggression because it interferes with higher-level cognitive processes that would otherwise inhibit aggression, allowing for perceived justification of retaliation (Anderson and Bushman, 2002).

Situation-Related Contributors to Aggressive Driving

Environmental Factors

The physical environment, both inside and outside the vehicle, can also affect the likelihood of driver aggression. High ambient temperatures can serve as an irritation (Kenrick and MacFarlane, 1986), whereas pleasant sounds or scents (e.g., peppermint) can soothe the driver (Raudenbush et al., 2009; Wiesenthal et al., 2000). The “weapons effect”, whereby the sight of a gun can increase aggressive behavior (Berkowitz and Lepage, 1967), has been demonstrated in the context of driving, with drivers engaging in more tailgating, speeding, horn honking, verbal aggression, and obscene gestures when a weapon was in their vehicle (Bushman et al., 2017; Hemenway et al., 2006; Miller et al., 2002). Similar findings have been demonstrated with less overtly aggressive stimuli, such as banners and billboards with aggressive text (Ellison-Potter et al., 2001). On the contrary, roadways with natural vegetation in view induce less stress than those surrounded by billboards and commercial buildings, and hence reduce the likelihood of aggressive driving (Parsons et al., 1998).

Driver aggression is typically elicited in response to a perceived offense by another driver (Wickens, Wiesenthal et al., 2011) and, depending on one’s disposition, may increase with repeated exposure to offensive roadway behavior (Chai and Zhao, 2016). Situational factors can further augment the risk of aggressive roadway retaliation. Traffic congestion can reduce frustration tolerance (Shinar, 1998), particularly when combined with a sense of time urgency (Wickens and Wiesenthal, 2005). Daily hassles and work-related stress can also impair one’s ability to tolerate a perceived injustice behind the wheel (Matthews et al., 1991; Wickens and Wiesenthal, 2005).

Visible features of the offending motorist can also influence attributions made for that motorist’s actions, affecting the likelihood of an aggressive response. Female offenders are perceived to be more careless and less aggressive than male offenders, suggesting that gender stereotypes operate in the roadway environment (Lawrence and Richardson, 2005), as has been discussed previously in this article. The relative status of vehicles involved in a roadway altercation can also increase or decrease the likelihood of expressed aggression (Doob and Gross, 1968). Tailgating in response to slow driving by a lead vehicle was greater when that lead vehicle was marked by a learner permit and less when that vehicle was an ambulance (Stephens and Groeger, 2014). Likewise, horn-honking latency in response to a middle-class vehicle stopped at a green light decreased with the relative status of the stopped vehicle, such that drivers of upper-class vehicles were quickest to honk and drivers of lower-class vehicles slowest to do so (Diekmann et al., 1996). Visibility of the “victim” motorist can also influence the likelihood of aggression. Greater anonymity associated with tinted windows, the dark of night, a hard-top vehicle (vs. a convertible), or a standard license plate (vs. a more memorable vanity plate), have been associated with more frequent roadway violations and driver aggression by an offended driver (Ellison et al., 1995; Ellison-Potter et al., 2001; Wiesenthal and Janovjak, 1992).

Aggressive Driving Countermeasures

The goal of identifying contributing factors is to develop means and methods to reduce aggressive driving. Comparatively less research, however, has focused on the effectiveness of potential countermeasures for aggressive driving.

Psychological Countermeasures

Programs to treat aggressive drivers are now being developed using cognitive-behavioral therapy, attributional retraining, and relaxation training (Galovski et al., 2006). These programs teach drivers to identify the triggers of their roadway anger and aggression, to recognize cognitive distortions that contribute to their anger, and to control their breathing and relax their muscles

when an anger-provoking event is encountered. These programs have been shown to successfully teach more effective coping strategies and alternative driving practices to help control aggressive outbursts (Galovski and Blanchard, 2004). Driver attributional retraining programs, for example, focus on making drivers aware of their cognitive biases when accounting for a perceived offense behind the wheel, encouraging drivers to focus on external factors (e.g., uncontrollable road conditions) as opposed to internal factors (e.g., intentional selfishness). One approach to attributional retraining that could prove very effective is to encourage drivers to focus on their own prior offenses; previous research has shown this focus to reduce anger in response to an offensive driving event (Takaku, 2006).

Environmental Countermeasures

Reducing aggressive behavior can also be aided by reducing the number of environmental stressors a motorist experiences such as unpleasant noises, odors, and temperature. Lavender and jasmine have been identified by aromatherapy research as calming smells, and may prove beneficial for reducing stress, irritability, and aggression while driving. The odor of peppermint has been found to reduce frustration and anxiety in a simulated driving task (Raudenbush et al., 2009). Listening to self-selected music has been found to reduce milder forms of aggressive driving such as rude hand gestures (Wiesenthal et al., 2003); however, a word of caution is necessary. While self-selected music may be beneficial, the selection of music should not distract the driver, the volume should not hinder a motorist's ability to hear other vehicles, and the tempo should be limited, as faster tempos have been associated with faster speeds and more roadway violations (Brodsky, 2002).

Enforcement Countermeasures

Several studies have identified the contribution of police enforcement to the reduction of driver aggression (Roseborough and Wiesenthal, 2014; Stanojević et al., 2018). Police presence may reduce aggressive driving for multiple reasons. Research has shown that upon witnessing an offensive driving behavior, victims experience increased happiness when a police vehicle stops the offending driver (Roseborough et al., 2018). Despite not being privy to the punishment the offending driver received (e.g., stern warning or citation), merely observing active enforcement in the driving environment seems to help reduce motorists' anger and aggression. Police presence may also stop offended drivers from retaliating aggressively by increasing the perceived likelihood of legal consequences for their own actions. Research has also contributed to enforcement efficacy by identifying more frequent or more offensively perceived aggressive driving behaviors, and when and where these acts are most commonly committed; this information is used to target limited enforcement resources more effectively (Stephens et al., 2016; Wickens, Roseborough et al., 2013; Wickens, Wiesenthal et al., 2013).

Technological Countermeasures

Technological countermeasures refer to both automobile and non-automobile technology. Recent advancements have led to the development of proximity sensors that notify a driver of an obstacle and automatically reduce the vehicle's speed when it closes in on another vehicle in order to maintain an appropriate distance; this technology could help to reduce instances of tailgating. Researchers have also suggested that automobile horn and front light control systems be modified to reduce repeated horn blowing and headlight flashing, introducing a required waiting period before the horn or lights are used again (Smart et al., 2005). While changes to vehicles may prove effective, designers and engineers must thoroughly understand the consequences of any changes; safe operation of the vehicle should never be compromised.

Despite their lack of popularity with drivers and the political controversy that results from that, both red light cameras and photo radar are widely used in Canada, Europe, and Australia and have been shown to reduce collision risk (Goldenbeld et al., 2019). In a similar vein, equipping motorways with an increased number of closed-circuit surveillance cameras designed to detect aggressive driving manoeuvres could help to reduce aggressive and risky driving behavior and assist authorities to apprehend aggressive drivers. The presence and efficacy of such cameras may have the same effect as actual law enforcement officers. Clearly identifying the presence of such cameras with signage would be essential, as would be public education about their efficacy.

Incentive Countermeasures

Some countermeasures focus on reinforcing or rewarding positive driver behavior. In 2010 speed cameras in Stockholm, Sweden were given a social twist. Drivers who obeyed the speed limit were automatically entered in a lottery with monetary prizes. During the lottery, over 24,800 vehicles passed the speed camera. Prior to the lottery, the average speed of a vehicle passing the camera was 32 km/h. After the lottery began, the average speed decreased to 25 km/h, a drop of 22%. The winner of the lottery won SEK 20,000 (approximately \$3,000 USD at the time) all of which was funded by the penalties paid by speeding motorists. As speeding is necessary for some aggressive behavior, such a campaign may help to reduce aggressive driving as well.

Recently, automobile insurance companies have been introducing rate reduction programs whereby insured drivers can elect to have their driving monitored (e.g., through a cellular phone application) and to earn reduced rates through safe driving practices. A 1-year evaluation of this type of pay-as-you-drive insurance program offered to young drivers in the Netherlands found a reduction in speed violations (Bolderdijk et al., 2011).

Multimedia-based Countermeasures

Multimedia campaigns targeting aggressive driving could also be effective. In Australia an advertising campaign was implemented targeting young male drivers who engaged in risky driving. The campaign conveyed a contemptuous sexual insult, suggesting that reckless speeding was the result of overcompensating for a deficit in young males' manhood. While previous fear-arousing campaigns were ineffective, there is evidence of this campaign's efficacy. There was a significant drop in speeding tickets and speed-related collision fatalities. In 2006, 64 young males (17–25 years of age) died in speed-related collisions. The number of fatalities dropped to 35 in 2007, the year "Pinkie" launched, and just 37 fatalities in 2008 (Roads and Traffic Authority, 2009). This campaign was likely more effective than others as it targeted a specific group of drivers (e.g., young males) and the specific motivation behind their behavior (e.g., impressing females).

Future Considerations

Efficacy of Countermeasure Research

From reading this article, it should be clear that much of what is known about aggressive driving revolves around contributing factors. Much less research has been devoted to countermeasure research. This article has discussed psychological, environmental, enforcement, technological, incentive, and multimedia-based countermeasures. Future research should employ sound methodology to assess the efficacy of such countermeasures. Furthermore, evaluation research should be conducted over an extended period to determine the longevity of any countermeasure influence on a behavior. The behavior in question should also be assessed prior to the implementation. All too often, countermeasures are implemented at the same time assessments of the negative behavior begin. In such cases, if changes in the negative behavior occur, they cannot be conclusively attributed to the countermeasure due to potential confounding variables.

Consolidation of Research

Psychology is advancing our knowledge of factors contributing to driver aggression, adding to the list of relevant variables and expanding our understanding of existing factors. Person-related and situational variables operate together; thus it is imperative that we continue to investigate how the contributions of multiple factors combine and interact to influence aggressive roadway behavior. We also need to understand the mechanisms underlying the influence of contributory factors. Personality, cognition, and affect all influence each other, and an improved assessment of the temporal order and strength of these influences is needed. Efforts to apply this information to modify driver aggression through policy, incentive-based approaches, psychotherapeutic programs (e.g., attributional retraining), and technological innovations to the vehicle and the roadway environment (e.g., electronic message boards) are in their infancy but possess great potential for impact.

Conclusion

In attempting to deal with the problem of aggressive driving, it is important to bear in mind that these behaviors have a variety of causative factors that have been summarized in this article. Given the diversity of factors, it is necessary to consider that no one suggestion is likely to reduce aggressive driving, but rather multiple approaches should be considered. When considering solutions, we urge that evaluation research be part of any program. Countermeasures need to be assessed for their efficacy, cost/benefits, and of course, political considerations.

Introduction

Without the intervention of maintenance personnel, equipment used in complex technological systems such as aviation, rail transport, and medicine would inevitably deteriorate to a point where safety and profitability would be threatened. After fuel, maintenance is the largest cost facing airlines (GRA Inc, 2007).

Despite advances such as Built-in Test Equipment (BITE), on-board sensors, and flight data monitoring, maintenance is still a largely human activity. Maintenance technicians work in an environment that is more hazardous than nearly all other jobs in the labor force. The work requires physical strength, dexterity, and balance, but also calls for clerical skills and attention to detail. The work may be carried out at heights, in confined spaces, in numbing cold or sweltering heat (Fig. 1). Communication can be difficult due to noise levels and the use of hearing protection. Although maintenance makes an essential contribution to system reliability, improper maintenance can be a major cause of system failure.

Maintenance activities can be divided into the two broad categories of preventative and corrective as shown in Fig. 2. Preventative maintenance includes lubrication, inspections, and other tasks that can be scheduled in advance. Many preventative tasks are performed regularly at airlines, sometimes daily or as part of a block of tasks such as an “A” check performed after hundreds of hours of flight. Other forms of preventative maintenance occur at greater intervals, sometimes bundled into “C” checks that may be scheduled yearly or less frequently, or heavy maintenance “D” checks. The airline industry currently outsources more than half of its preventative maintenance tasks to specialized Maintenance Repair and Overhaul (MRO) organizations.

In the early years of the airline industry, each airline developed its own preventative maintenance program that called for intensive maintenance at predetermined intervals. These programs sometimes required the complete overhaul of systems, regardless of whether the maintenance was necessary or effective. In the 1970s, there was an increasing realization that scheduled maintenance programs needed to be tailored to the needs of each component or system, based on the failure patterns of each component, and the consequences should a failure occur. Today, regulators, manufacturers, and airlines work together to develop maintenance programs for aircraft fleets based on Reliability Centered Maintenance principles (Moubray, 2001) as outlined in a document known as MSG-3 (Maintenance Steering Group). This approach ensures that systems are maintained at an appropriate level, while avoiding over-maintenance and the increased potential for error that this introduces.

Corrective maintenance, also known as unscheduled maintenance, is performed in response to unplanned operational events such as aircraft damage, component failure, or defects discovered during a scheduled check. Corrective maintenance includes fault isolation, repair, and replacement of faulty components. Although some corrective tasks are minor, others require extensive system knowledge, problem solving, and specialized skills. Some nonscheduled inspections are initiated in response to events such as a bird strikes, lightning strikes, and heavy landings. These inspections are sometimes referred to as “Chapter 5” inspections as they are found in this chapter of maintenance manuals following the industry-standard ATA numbering system. Major nonscheduled

Figure 1 A maintenance technician at work. *Source: Image courtesy of American Airlines*

Figure 2 Major categories of maintenance. *Source: US DoD (1997)*

maintenance can be particularly disruptive and expensive for airlines. An “Aircraft on Ground” (AOG) requires an immediate response that may include flying maintenance personnel to the stranded aircraft, rapidly locating spare parts, and coordinating with the original equipment manufacturer.

Maintenance Steering Group-3 defines three levels of inspections: general visual, detailed, and special detailed. General visual inspections are carried out within touching distance of the area being examined, to detect obvious damage such as clearly visible cracks, corrosion or dents. These inspections do not require special equipment, although ladders or workstands may be used, and there may be a need to open access panels. Detailed inspections involve intense visual and/or tactile examination for less obvious defects, sometimes with the use of lenses or mirrors. There may also be a need for extensive disassembly to gain access to the area to be inspected. Lastly, special detailed inspections are examinations of an area involving the use of non-destructive inspection (NDI) techniques. These include ultrasound, thermography, X-ray, and dye penetrant techniques. The effectiveness of inspections relies on the ability of the inspector to detect the sensory signs that could indicate a defect, and then decide whether a defect is actually present. Factors such as lighting, time of day, monotony, vigilance, and the adequacy of rest breaks can all impact inspector performance (Drury and Watson, 2002).

Maintenance Personnel

In many countries, including those covered by the rules of the European Aviation Safety Agency (EASA), aircraft maintenance licenses are divided into two basic categories. The first category enables the technician to certify work on structures, engines, mechanical, and electrical systems. The second category applies to avionics (the electronic systems used on aircraft). Some personnel possess both licenses or additional qualifications providing further signature authority. In most cases a licensed technician with the appropriate type rating has the authority to certify that their own work or that of a colleague was performed correctly.

In the United States, qualified maintenance mechanics are referred to as Aviation Maintenance Technicians (AMTs) or Airframe and Powerplant technicians (A&Ps). Unlike other regulatory authorities, the US Federal Aviation Administration (FAA) does not require technicians to possess a specialized qualification to work on avionics systems. The FAA system also relies on independent inspectors as part of the quality control process. In addition to performing general and specialized inspections of structures and components, quality control inspectors certify that critical tasks have been performed correctly by AMTs.

Quality Lapses in Maintenance

According to the International Air Transport Association, improper maintenance was a factor in 17% of airline accidents in the period 2014–18 (IATA, 2019). Maintenance errors not only pose a threat to flight safety, but can also impose significant financial costs through delays, cancellations, diversions, and schedule disruptions. For example, in the case of a large wide-body airliner, a flight cancellation can cost the airline around USD \$200,000, while delays at the gate can cost over USD \$20,000 per hour. Therefore, even a small reduction in minor maintenance problems can result in major savings for the airline.

Throughout the 1980s and 1990s, a series of landmark accidents drew attention to the fact that aircraft inspection and maintenance relies on human performance. Improvements in the quality and efficiency of maintenance requires an understanding of the capabilities and limitations of maintenance personnel.

Improper maintenance was a primary factor in the world's worst single-aircraft accident, an event that claimed 520 lives. The 747-100 was on a short domestic flight in Japan when it experienced a sudden decompression due to the failure of the aft pressure bulkhead. The escaping air caused most of the vertical stabilizer and rudder to separate, and a loss of hydraulics pressure from all four systems. The pilots attempted to maneuver the aircraft using engine power, however they were unable to maintain control and after about 30 min the aircraft crashed into a mountain north west of Tokyo.

The investigators found that the aft pressure bulkhead had failed in flight due to a fatigue fracture in an area where a repair had been made seven years previously. The repair had involved replacing the lower half of the bulkhead. The new lower half should have been spliced to the upper half using a doubler plate that would have extended under three lines of rivets. However, part of the splice was made using two plates instead of a single plate as intended (Fig. 3). As a result, the join relied on only a single row of rivets. After the repair, the aircraft flew over 12,000 flights and underwent six C checks before the accident occurred (Japan Ministry of Transport, 1987).

In April 1988, an Aloha Airlines Boeing 737-200 en-route to Honolulu experienced an explosive decompression in which approximately 18 ft of cabin skin and structure separated from the aircraft. The pilots were able to make an emergency landing, however the accident resulted in one death and eight serious injuries. The NTSB determined that the accident was caused by the failure of the airline to detect the presence of significant disbonding and fatigue damage that ultimately led to the failure (National

Figure 3 The repair to the aft pressure bulkhead as specified in the repair instructions (at left), and repair as actually carried out (on right). Note gap of doubler plate between top two rivets. Source: Terada and Kobayashi (2006).

Transportation Safety Board, 1989). As a result of the accident, the human factors of inspection became a major issue of concern, particularly in the United States, where the FAA sponsored an extensive research program on the topic. Details of the FAA work can be found in the recommended reading.

Little more than a year after the Aloha accident, inspection was once more the focus of attention when a United Airlines DC-10 suffered a catastrophic engine failure that damaged the aircraft's hydraulic system, resulting in a loss of flight controls. In a remarkable feat of airmanship, the crew was able to partially control the aircraft for a crash landing using engine thrust alone. 111 passengers died, however 175 passengers and 10 crewmembers survived. The engine failure occurred when the stage 1 fan rotor disk separated from the center engine as a result of an undetected fatigue crack. Fifteen months prior to the accident, the component had been inspected using a dye penetrant technique. A fluorescent fluid was applied to the component, which was then inspected under ultraviolet light to reveal the presence of cracks or discontinuities, however the inspection failed to find a 0.5 inch long fatigue crack. The [National Transportation Safety Board \(1990\)](#) concluded that the root cause of the accident was inadequate consideration of human factors limitations in the inspection and quality control procedures.

Human Factors in Maintenance

The accidents described above, and others like them, led to a major worldwide effort to understand the human factors of airline maintenance. Research sponsored by the FAA, Transport Canada, and other agencies has brought to light the unique human factors of maintenance and inspection. The lessons are now being applied by operators and regulatory authorities worldwide.

Some of the most commonly observed lapses in maintenance are:

- Equipment or part not installed (typically small parts such as O-rings or washers)
- Failure to detect damage during inspection
- Incomplete installation—often a nut or fastener left “finger tight” and not torqued
- Cross connections—electrical wiring or control cables
- Wrong parts fitted
- Parts fitted in the wrong location or orientation
- Loose objects or tools left in aircraft
- Panels, caps, or cowlings not secured.

Some maintenance quality lapses may remain undetected for months or years before discovery, or until an operational consequence occurs. Without doubt, some maintenance irregularities are never detected, and continue to fly with the aircraft until the end of its service life. Quality lapses in maintenance usually involve one or more human errors, however the culture of maintenance has tended to discourage the open reporting of minor maintenance errors. In recent years, confidential incident reporting systems and the application of “just culture” concepts has enabled the industry to gain a better understanding of the nature of maintenance error.

Human Error in Maintenance

Maintenance personnel make an invaluable and essential contribution to continuing airworthiness. As with all complex human/machine systems, however, some level of human error is inevitable, and the use of the term “error” should not automatically imply blame or fault. While individual human errors cannot be predicted, estimates of error rates are used widely in risk assessments. **Table 1** shows estimated error probabilities for maintenance tasks, based on military data. The reader should note that these numbers, although useful, should be seen as “best guesses,” to be treated with an appropriate level of skepticism. Error rates will vary according to the nature of the task, the environment, training, and other factors. Nevertheless, rates such as these can provide a general awareness of the level of risk introduced by human error. Although the probability of error for each instance of a task may be relatively low, if the task is performed numerous times, the overall chance of an error can become high.

Table 1 Estimated probabilities of maintenance errors

<i>Task</i>	<i>Estimated chance of error during task</i>
Install nuts and bolts	0.2%
Connect electrical cable	0.3%
Install O-ring	0.3%
Tighten nuts and bolts	0.4%
Read pressure gauge	1.1%
Install lock wire	3.2%
Check for error in another person's work	10.0%

Source: [Gertman and Blackman \(1993\)](#).

In some cases, particularly if a maintenance error has been discovered or reported in a timely manner, it will be possible to examine not only the observable outcome of the error (such as failing to tighten a nut), but also the thinking processes that led the technician to make the error. Human factors analysis not only gives us a powerful insight into the origins of the error, but also helps us develop ways to prevent or capture future errors. Applying human error models to maintenance discrepancies reveals that underlying these events are a limited range of cognitive error forms. More than 50% of the maintenance errors in the aviation industry can be placed in one of four categories: memory failures, procedural noncompliance, assumption errors, and knowledge-based errors (Hobbs and Williamson, 2003).

Memory Failures

One of the most common errors in maintenance incidents is memory failure. Rather than forgetting something about the past, the technician typically forgets to perform an action that they had intended to perform at some time in the future. Psychologists refer to memory for intentions as prospective memory. Two common examples are forgetting to reconnect a disconnected system at the end of a task and leaving an oil cap unsecured. Failures of prospective memory are particularly likely when a maintenance task has been interrupted and must be picked up again later.

Procedural Noncompliance

An aircraft hangar is a highly regulated workplace. Technicians are expected to carry out their duties while observing legal requirements, manufacturer's maintenance manuals, company procedures, and unwritten norms of safe behavior.

When asked about their most recent task, 34% of aircraft maintenance technicians in Europe acknowledged that they had not strictly complied with the formal procedures (McDonald et al., 2000). Examples are, signing off a task before it was completed, and performing a task without the correct tools or equipment. In most of these cases, the maintainer could probably have justified their actions, nevertheless the ubiquity of procedural noncompliance indicates a common divergence between formal procedures and actual task performance.

Assumption Errors

An assumption error occurs when a person misidentifies a situation, or fails to check that their understanding of a situation is correct. False assumptions usually occur in familiar situations where the person has the expertise to deal with the task. In maintenance, this commonly takes the form of a misunderstanding between colleagues, such as incorrectly assuming that another person has performed a task step. Careful communication is essential for effective shift handovers, when work-in-progress is continued from one shift to another.

Knowledge-Based Errors

The term "knowledge-based error" refers to mistakes arising from either failed problem-solving or a lack of system knowledge. Most maintenance technicians enjoy variety in their work, but to achieve this, they must be assigned unfamiliar tasks from time to time. Many maintenance technicians report that they experience some level of uncertainty when performing such tasks. Ambiguities encountered during the preparation stage, such as unclear procedures, may set the scene for errors that will emerge later in the task. Supervisors must ensure that technicians are able to draw on the support of experienced personnel whenever they are assigned nonroutine or challenging tasks.

Performance-Shaping Factors in Maintenance

Although some workplace errors or deviations from procedures reflect random variability in human performance, most are related to performance-shaping factors in the workplace. Some of the most common factors in maintenance incidents are time pressure, interruptions, fatigue, and documented procedures that are inadequate for the task. Memory lapses are often associated with interruptions and fatigue; procedural noncompliance is known to occur in response to both time pressure and inadequate procedures. Assumption errors are more likely when there is inadequate communication and coordination between technicians.

A widely-recognized description of error-producing conditions in maintenance is the "Dirty Dozen" developed by Gordon Dupont at Transport Canada. This list of 12 factors is commonly used in human factors training for maintenance technicians.

The Dirty Dozen Maintenance Human Factors are:

1. Lack of communication
2. Complacency
3. Lack of knowledge
4. Distraction

5. Lack of teamwork
6. Fatigue
7. Lack of resources (including documentation, parts, staffing)
8. Pressure (externally and self-imposed)
9. Lack of assertiveness
10. Stress
11. Lack of awareness
12. Norms

Interventions to Improve the Quality of Maintenance and Inspection

The remainder of this section describes several interventions that can lead to improved human performance in maintenance. These interventions are; nontechnical skills training, improved documentation and procedures, design for maintainability, fatigue management, and learning from incidents.

Nontechnical Skills Training

The International Civil Aviation Organization (ICAO), the European Aviation Safety Agency (EASA), Transport Canada, the Australian Civil Aviation Safety Authority, and many other regulatory agencies require maintenance staff to have an understanding of human factors principles. While stopping short of requiring such training, the FAA has released extensive educational material on maintenance human factors.

EASA (Part 66) requires that human factors knowledge is included among the basic initial knowledge requirements for certifying maintenance staff on commercial air transport aircraft. EASA (Part 145) requires that maintenance organizations provide regular human factors training to staff. The training is required not only for certifying staff, engineers, and technicians, but also for managers, supervisors, store personnel, and others. Human factors continuation training must occur every two years. Over 60 human factors topics are listed in the guidance material associated with the EASA regulation, including violations, peer pressure, memory limitations, workload management, teamwork, assertiveness, and disciplinary policies. The EASA human factors requirements are becoming a de-facto standard, even in regions of the world not regulated by EASA.

Improved Documentation and Procedures

According to the [FAA \(2012\)](#), aviation maintenance personnel spend between 25% and 40% of their time dealing with maintenance documentation. Poor documentation is one of the leading causes of maintenance incidents, and maintainers often report that procedures do not fully meet their needs ([Chaparro and Groff, 2002](#)). Documentation can be particularly challenging at MROs where technicians must switch between the maintenance procedures of different airlines.

There are some very basic aspects of document design that can have a major impact on the usability of a document. The Simplified Technical English specification developed by the [AeroSpace and Defence Industries Association of Europe \(2017\)](#) can help to create succinct and unambiguous text. This is particularly crucial when the reader has a first language other than English. Simplified English is used widely in the production of aerospace manuals and is now used by both Boeing and Airbus. Simplified English limits the number of words used to describe steps, and also ensures that each word only has one meaning. For example, in everyday English the word “tap” could have several different meanings including the tap above a sink, the action of removing fluid from something, or to listen in on a telephone conversation. In simplified English, “Tap” only has the meaning of to hit something, as in “tap with a hammer.”

Improving documentation is one of the most cost-effective ways to improve quality and reduce maintenance error. Maintenance organizations generally have systems to allow personnel to report problems and make suggestions for improvements in documentation. In many cases however, mechanics express frustration at the slow pace of such systems and the lack of responses to their suggestions.

Design for Maintainability

Significant improvements in cockpit design and layout have occurred since WWII. Yet the design of equipment for ease of maintenance has received less attention. Poor design is a major factor leading to maintenance problems. Examples include:

- Plumbing or electrical connections that permit cross connection
- Components that are difficult to reach, particularly where unrelated components must be disconnected to enable access
- Obstructions to vision
- Procedures that require levels of precision or force that are difficult for the technician to deliver
- Components that can be installed in the reverse sense.

Table 2 Examples of maintainability guidelines in Military Handbook 470-A

Guidelines number	Description
EC-26	Avoid using identical electrical connectors in adjacent areas.
EC-15	The removal or replacement of electronic equipment should not require the removal of any other piece of equipment.
EC-24	Use electrical connectors that incorporate alignment key-ways to reduce incidence of damage due to improper engagement.
ENG (G)-12	Provide a clear and viewable access envelope to fuel and oil filters.
CONT-06	Design all cables and brackets associated with cable installations, so they are accessible by a 75 percentile male hand.

Design standards such as the US Department of Defense Handbook 470-A contain numerous guidelines for maintainability, many of which have relevance to aircraft design (Department of Defense, 1997). Illustrative examples are listed in [Table 2](#).

Fatigue Management

Aviation maintenance personnel face a heightened risk of fatigue due to night shift work, the potential for long duty times, and the sleep disruption that can result from these working arrangements.

In recent years, comprehensive Fatigue Risk Management Systems (FRMS) have been applied to aviation maintenance (FAA, 2016). An FRMS is a data driven and scientific approach to fatigue management that utilizes a range of strategies. Some of these interventions assist the individual; examples are educational material, medical screening, and treatment of sleep disorders. Other interventions are aimed at tasks. These include avoiding the scheduling of critical tasks during times of heightened fatigue risk, and keeping the most critical tasks out of the hands of the most fatigued people (progressive restriction of responsibilities). A typical FRMS will also include a statement of policy and management commitment, a risk assessment strategy, and an incident reporting and analysis system. At the core of most FRMS are limits on the working hours of maintenance personnel.

Professor Simon Folkard has developed a set of widely-adopted working hours guidelines for airline maintenance technicians. They can be found in full on the website of the UK Civil Aviation Authority (CAA). Five key items from Folkard's guidelines are:

- There should be a 12-h limit on shift duration
- No shift should be extended beyond 13 h by overtime
- A break of at least 11 h should occur between shifts
- There should be a work break every 4 h
- A month's notice of work schedules should be provided.

Learning from Incidents

Incident reports are one of the few channels for organizations to identify organizational problems in maintenance, yet the culture of maintenance around the world has tended to discourage the open reporting of maintenance incidents. This is because the response to errors has frequently been punitive. In some companies, technicians who make errors will be punished by days without pay, or even instant dismissal. It is hardly surprising that many minor maintenance incidents are never officially reported.

A growing trend around the world is to encourage incident reporting in maintenance by giving reporters limited immunity from disciplinary action or prosecution. David Marx, an aeronautical engineer and lawyer, has promoted the idea of a "just culture" in which some unsafe acts will result in discipline, however most will not. Marx divides unsafe actions of people into four overlapping categories: (1) Human error, (2) Negligence, (3) Recklessness, and (4) Intentional rule violations. Negligence is a failure to recognize a risk that should have been recognized. Recklessness is a conscious disregard for a visible significant risk.

Part 145 of the EASA regulations requires maintenance organizations to have an internal occurrence reporting scheme that enables occurrences, including those related to human error, to be reported and analyzed.

In the United States, the FAA encourages airlines and repair stations to introduce Aviation Safety Action Programs (ASAP) that allow employees to report safety issues with an emphasis on corrective action rather than discipline. Incident reports are passed to an event review committee comprising representatives of the FAA, management, and unions.

Several investigation techniques have been developed specifically for airline maintenance events. The best known is Boeing's Maintenance Event Decision Aid (MEDA) which includes a comprehensive list of event descriptors, such as "access panel not closed" and then guides the investigator in identifying the contributing factors that led to the event. Over 70 contributing factors are listed, including fatigue, inadequate knowledge, and time constraints.

Investigators typically find that major accidents are preceded by numerous minor events. Minor everyday close-calls or incidents can serve as raw materials for a safety evaluation system. An example of such an approach is the 38-item Maintenance Environment Questionnaire (MEQ) (Hobbs, 2005).

The MEQ assesses the extent of seven error-producing conditions in maintenance workplaces: Fatigue, coordination, time pressure, knowledge, supervision, availability of parts and equipment, and procedures. The MEQ can supplement incident

Figure 4 Example of a maintenance environment questionnaire profile.

investigations by providing a large amount of information on workplace human factors to enable comparisons with industry norms (Fig. 4).

The Future of Maintenance and Inspection

Emerging technologies have the potential to significantly change the processes involved in aircraft maintenance and inspection. Today, airline maintenance personnel routinely receive performance data from aircraft in-flight. This enables emerging problems with engines or other systems to be anticipated and diagnosed before the aircraft arrives at the gate, thereby reducing schedule disruptions.

For inspection, developments include more effective nondestructive inspection (NDI) techniques, smart materials with the ability to indicate damage through observable “bruising,” and structural health monitoring (SHM). The ability to readily transmit information over the web is enabling NDI results to be interpreted in real-time by personnel remote from the structure being examined. Several airlines are currently testing drones to assist in structural inspections. Data from permanently-placed sensors can be used as part of an SHM program. Benefits include reduced inspection times and the ability to monitor difficult-to-access areas of the airframe without the need to create access for a technician.

Despite advances in technology, the airline industry will continue to rely on the perceptual capabilities, judgment, teamwork, and communication skills of maintenance personnel. Airline travel is now the safest mode of transport. Part of the reason for this is that the industry has continuously learned and applied knowledge from the field of human factors to maximize the performance of maintenance personnel and drive down the rate of maintenance error.

Definitions and Goals

To understand airport security, let's start with definitions, which in turn, lead to goals and then to how to try and achieve these goals. *Security* commonly refers to deterring and minimizing acts intended to cause human death and injury; non-human destruction and damage; exploitation and the unauthorized modification, access, and transmittal of information, often affecting important processes; and threats to violate deterrence and minimization. Less commonly, security refers to being comfortable with how attempts to deter and minimize are being managed. Without such comfort, there's psychological injury, which in turn, can lead to noxious consequences that are political, economic, social, cultural, and even spiritual. In aviation, such consequences can lead to anything from fewer people wishing to fly to reduced use of airport concessions; less financial profit and more loss for airlines and aircraft producers, parts suppliers, and maintenance organizations and personnel; a smaller aviation-related tax base; and spreading and interactive economic, political, and socio-cultural dislocations from the local to the global.

In defining *security*, it's important to note synergistic, agonistic, and antagonistic effects between it and generic *safety*. Often, but not always, *security* and *safety* only differ in the intent of the act being deterred or minimized. Often, but not always, activities to support one will support the other. Too often, a safety problem even with a solution serves as a "free experiment" for those seeking to harm security, for example, a safety fix indicates how security can be harmed through an "unfix." Less often, a security problem may be resolved in a manner harming safety, and ironically, security, for example, stacked up automobile traffic at an inspection checkpoint to an airport entrance leading drivers to be less safe and secure. Another example of a "free experiment" comprises unintentional violations of security and safety procedures that can serve as inspiration for intentional violations and their ineluctable sequelae.

In defining *security*, it's also important to note that changes in government, business, and academic leadership can lead to different interpretations, reprioritizations, and identifications of the acts to be deterred or minimized. The same applies to what qualifies as acceptable psychological comfort to estimated degrees of deterrence and minimization. As well, to whether deterring and minimizing acts are more or less important than the actual consequences of the acts.

The same applies to changes within the global population and various general publics as to sociocultural values bearing on the differential import of various acts versus consequences, mortality, morbidity, and whether security authorities and those seeking to harm security are operating by their own choice or by factors beyond their control. (This choice versus control distinction affects beliefs in how much one can be protected and, thus, how psychologically comfortable one is in specific situations). Those who seek to harm security will be well ahead of the game, if they understand how a target's sociocultural values yield exploitable opportunities.

More briefly to the definition of *airport*. It commonly refers to a locus of incoming and outgoing aircraft—piloted fixed wing and rotary, and unmanned—with variations on size, management and servicing support, concurrent amenities, and embedding within larger physical, political, economic, and sociocultural contexts. The present analysis is intended to cover all loci of flight, especially, commercial flight. Exceptions, for example, government, military, corporate, other private, and personal aviation, will be noted as appropriate. Another important distinction is that of objective and subjective conceptions of *airport*, especially, as to boundaries. Often enough, there are differences between the legal, the operational, the security-relevant, and the mental constructs and images harbored by personnel. All have impact on what security is, what to do, and what can be done about it.

Laws/Policies/Regulations/Programs/Operating Instructions

There continue to be a patchwork of global, regional, international, national, and local documents—laws, policies, regulations, programs, and operating instructions—affecting aviation and, ineluctably, airports. This patchwork is largely created by

governmental, military, corporate, professional, and other public and private entities. This results in real and potential turf battles, ambiguities, and contradictions and differences of interpretation and application. This impedes optimal assessment, planning, implementation, and re-assessment of aviation and airport security. Specifically, there are problems with how many personnel formally involved in airport security should have a need-to-know, about what they need to know, and what they know so as to be aware of, understand, remember, and comply with and all relevant documents. Documents commonly cited with significant airport security impact—even as they vary in how often they are corrected, rescinded, or otherwise modified—include the International Civil Aviation Organization's (ICAO) *Aviation Security Manual (Doc 8973—Restricted)*, the *China Civil Aviation—Regulations & Security Check*, the *United States' Aviation and Transportation Security Act (ATSA)*, P.L. 107-71, and a myriad of airport-specific operating instructions.

Not only documents, but also definitions and goals within them can change based on new developments in basic and applied research and technology, as well as politics pertaining to and transcending aviation and transportation. These developments can change the meaning of existing words, induce neologisms, and stimulate new ways of thinking about airport security—in other words, the underlying epistemic structures of security knowledge is up for grabs.

One other vehicle of change involves *looping effects* (Hacking, 2006). As an example, security authorities develop concepts, definitions, and estimates of types of people judged more likely to harm security including how they might harm it, for example, combinations of psychological predispositions and behaviors. Airport security policies and programs are based on these types. Paradoxically, those intending to harm security can actually take on aspects of these concepts, definitions, and types—much as how criminals just beginning a life of crime and those already well advanced craft portions of their identities based on what they view in commercial films. It's as if they're being explicitly and implicitly schooled in harming security-by-security authorities. But then their psychological dispositions and behaviors begin to drift—as they develop different and more effective ways to harm security, and violate security authorities' expectations based on the original concepts, definitions, and types. So the security authorities make changes based on new information and interpretations, and an iterative cycle among authorities and those intending to harm security fade in and out of public discourse and the texts of implanting security documents. One consequence of all of this is that different security authorities may end up talking above, below, and around each other and the people with whom they provide protective and consulting services. Another is that the very changes in concepts, definitions, and types have a direct, tangible effect on the world one is trying to protect.

Threats, Vulnerabilities, and Risks

Once definitions, goals, and various implementing documents are considered as an overarching context, it becomes quickly obvious that there are infinite security needs but only finite security resources (money, people, things, and processes) to satisfy these needs. Prioritization of needs and resources is essential, and this occurs through the integration of *threat*, *vulnerability*, and *risk*. Prioritization is also difficult given the interdependence of security with the political, economic, social, and cultural aspects.

Threats

Threat refers to the, who, what, when, how, why, and where of those who seek to impede the deterrence and minimization of acts harmful to security. There are three main classes of *threat*—terrorism, non-ideological crime, and emotional and mental dispositions and disorders. These are pure types, which can often be at least partially linked and mixed for specific people and situations. Accurate threat assessment is most importantly based on intelligence collection and analysis, then the production and secure transmission of intelligence products to security personnel with a need to know. Different security personnel dependent on their responsibilities will have different needs to know and on their psychological capabilities different understandings of what they know (Elias, 2009).

Terrorism. Quite simply, *terrorism* refers to ideologically motivated acts to harm security. *Ideology* refers to a belief system of how the world works, should work, and is working—especially who should get finite resources in a world of infinite needs. Terrorist ideologies usually are religious and/or political in nature—the sacred and the secular. It is essential to note that terrorism is ultimately psychological in nature. Its ultimate purpose is not to destroy, damage, or threaten. These consequences are mere way stations to achieve some ideologically desired behavioral change in the world via psychological impact on those who become aware of the terrorist act and have the ability to make the desired behavioral change. For example, changing the religious and/or political policies and acts of others, inducing certain people judged foreign to leave a domestic areas, and to remove human and material contaminants from the world.

Terrorists are motivated ideologically through their psychologies, and without ultimately focusing on changing the content and attraction of such motivators, counter terrorists' stacking up high body counts may only induce more people to become terrorists and take the place of the dead. The dead then beget the living. Often enough with some religiously and even some secularly based terrorisms, one's own death becomes not a deterrent but an attractor, something to aspire to—for example, desired suicide through counter terrorism policy.

Finally, airports and aviation are lucrative, psychological targets for terrorists. More and more people rely on aviation for work and play—for living. There can be significant noxious effects on economies and the hearts, minds, souls, and behaviors of people from the global to the local. And even in intellectual history, the very act of flying has been interpreted as symbolic of human striving and progress, hopes, and desires—now to be dashed through terrorism. So, in a macabre fashion, airports and aviation are alluring venues to reach out and touch someone via terrorism. This allure also explains why the so-called "lone wolf" terrorist

phenomenon is bogus. A lone individual thinks and feels and imagines within a mind full of people met, people to meet, and people just envisaged and constructed. The lone individual is never alone with the right technology—and with creative thought, this can be quite primitive—some portion of aviation can be brought to its knees along with the sequelae. Perhaps controversially, governments and their military and intelligence entities, businesses, and various non-state actors from the individual through the organizational can be initiators, targets, and observers of terrorism. The airport is one locus ready for action and to be acted upon.

Non-ideological crime. Philosophers and sociologists of crime might argue that all crime is ideological in that it involves violating legal, ethical, and moral proscriptions antithetical to an ideology. But here the *non-ideological* refers to instrumental behaviors leading to material gain. For example, theft, trafficking, and catering to illicit needs of the traveling public—namely, intersections of aviation with other transportation modalities—and people throughout the world. In fact, airports are an alluring criminal venue not just for the people and commodities passing through, but as a locus to satisfy the illicit needs of the population adjacent to airports and of those who will travel to the airport for illicit satisfaction. Non-ideological crime conflates with terrorism, when airport personnel are suborned to engage in behavior to facilitate a terrorist act—not for ideology but for remuneration. An example includes, bribing someone to look the other way or provide information supporting terrorism. So is creating a spot for an individual within a non-ideological criminal enterprise to facilitate terrorist activity. Non-ideological crime can also be constituted by or intersect with corruption, mismanagement, and purposeful hiring of people without appropriate capabilities and motivations that directly or indirectly impact on security (Bunn et al., 2016).

Emotional and mental dispositions and disorders. Instead of the ideological strivings of terrorists and instrumental desires of non-ideological criminals, people may harm security as an expression of combinations of conscious and unconscious psychological conflict. Or through limited intellectual and emotional faculties, they may not understand what they're doing or be easily exploited by others. Or their behavior may be largely influenced by problematic emotional self-regulation and by personality dispositions and traits such as, sensation seeking and those termed the dark tetrad—narcissism, Machiavellianism, psychopathy, and sadism.

When unconscious psychological conflict, certain disorders, and limited psychological faculties are paramount, these people are less likely to engage in sophisticated strategic planning, coherently work with other plotters, or effectively employ any but the most primitive technology. The airport and aviation can become symbols and portals of psychological conflict, at times even psychological containers for troubling thoughts, feelings, and motives that are difficult to manage. Harming security violations become more common when the container leaks or breaks. Even when ineffectual, their attempts to violate security serve as free experiments for terrorists and the non-ideological criminal who can observe how security personnel respond.

Depending on much one is in the throes of sensation seeking and the dark tetrad; one may manifest behavior and effectiveness as if one is primarily a terrorist or non-ideological criminal. Effectiveness often is dependent on indoctrination within religious schools and gatherings, prisons, or the social clubs of gangsters and racketeers.

Finally, there are some members of mental health professions who deny the existence of emotional and mental disorders, but instead label them as sane responses to insane societies. They may be correct, but the threat remains for security personnel. One relevant implication may be that the label of an emotional or mental disorder applied to an individual may provoke the intent to harm security. Another is that national and local mental health and social services policies, for example, community versus institutional care and inevitable shortfalls—can affect intensity and frequency of this threat.

Vulnerability

Vulnerability simply refers to everything that can be wittingly or unwittingly exploited by those who seek to harm security. At issue are *people, things, process, and money*. *People* examples include, the motivations, abilities, knowledge, and personalities of security personnel. *Thing* examples include, the density of walls, the fidelity of explosive detection or remote sensing technology, the weapons carried or un-carried by security personnel, and the situatedness of an airport as to topography, topology, and adjacent populations. *Process* examples include, the take-off and landing routes of airplanes; ticketing and security rules of engagement; and human resource management procedures including education, training, and recognition programs for security personnel. (*Process* actually encompasses how any activity is structured, what it's supposed to do, and how it does it—all potentially exploitable to harm security).

The amount of *money* dedicated to support security and anything affecting security—as well as security expertise, politics, social and cultural factors (including the security cultures at an airport and organizations formally and informally impacting on airports), and resulting budget priorities often drive the potential for exploitation by those seeking to harm security. Everything identified as vulnerability, should be prioritized as to impact on security if exploited in a particular manner.

Risk

Risk refers to the matching up of *threat* to *vulnerability*. Significant *vulnerabilities* might be obviated, if the likelihood of *threat* based on intelligence collection and analysis is low. Less significant *vulnerabilities* might be strongly attended to, if the *threat* is deemed significantly high. Ultimately, these are political questions, sometime but not always informed by security expertise. This is because *risk* cannot be fully met even if all existing resources were applied to it. And, obviously, airport and aviation security is not the only game in town—cf. education, health, and various material needs of population; shareholder needs of private industry; other security needs of intelligence, security, and law enforcement organizations.

Besides attempts to assess the ideological attractiveness of airports and aviation for those who seek to harm security described in *Terrorism*, and the economic attractiveness mentioned in *Non-political crime*, quite difficult to identify is what psychologists call the *Icarus complex* and which is relevant to all three categories of *threat* including that of *Emotional and mental dispositions and disorder*. The origins of the complex's name go back to the ancient Greek myth of Daedalus and Icarus, wherein the latter flew too close to the sun and tumbled to his demise as the wax securing his wings melted. The intrinsic attractions of airports and aviation in the eyes of various bad actors both elicits motivation to harm security and can cause overshooting what's possible for an impossible dream.

Airport Security Capabilities

Layers of security. An integrated layering of money, people, things, and process constitute optimal airport security. The ideal goal is to continuously change layers as calculations of threats, vulnerabilities, and risks continuously change. What follows are common examples. One important conclusion will be that the layers should be both offensive and defensive, —for example, information operations to decrease the number of people who intend to harm security or support those who do; proactive and pre-emptive apprehension of bad actors physically distant from an airport; hardening of aircraft and airport infrastructure against explosive harm; fine-tuning of weapons, weapons components, and explosive trace detection within the airport; upping the validity of various data mining and behavioral detection programs; and, again, information operations, here to lessen the likelihood that the ultimate psychological targets of terrorism will, succumb to behavioral change—and concurrent information operations to promulgate this to the world.

Intelligence. By far the most important airport security capability comprises robust intelligence activities. As previously described, collection and analysis, and then production and transmittal, of relevant information can often elicit relevant *threat* data to be integrated with *vulnerabilities* and then yield a more useful risk assessment. In turn, airport security authorities and personnel can more likely optimize the effectiveness of layers of security. This information also can facilitate identification of actual or incipient bad actors and their support structures (Fox and Farmington, 2018). People seeking to harm security along with their supporters can be impeded or seized, and then detained, interrogated, adjudicated, and imprisoned, if appropriate.

As well, covert and clandestine activities—especially those with counterintelligence significance—can penetrate networks, shape behavior away from harming security, and even foster and guide conflict among those intending to harm security. These activities also can influence planning so that the various threats will be less likely to be effective and more likely to be matched with vulnerabilities that mitigate harmful consequences.

Overt, covert, and clandestine information operations can be crafted specific to various societies, cultures, and subpopulations to decrease the desire to harm security including airport security. The essence of this would be reinforcing more and more people with a coherent identity, a narrative to believe in, and social networks obviating the need for harming security.

More controversially, information operations can target general publics, so that their psychological reactions of fear, panic, dismay, and inclination to pressure their governments to do the wrong things are minimized. This last especially gets at the lifeblood of terrorism. If information operations by intelligence personnel against a domestic population by its government are proscribed, the role should fall to government-business-academic-civic-communications media partnerships overtly explaining the ultimate psychological purposes of terrorists, and what general publics can do not to become unwitting psychological victims. Other intelligence activities can help ameliorate political, economic, social, and cultural realities that help fuel the three major threats to airport and aviation security.

Effective intelligence activities can help prevent harm to security many miles and time zones from a specific airport. But as with all airport security capabilities and all threats to security, the best that can be done is to reduce the risk not do away with it. Like all of the oldest professions in human history, there probably are significant evolutionary phenomena impelling threat and impeding its disappearance from the human behavioral repertoire.

Planning and designing airports. As already alluded to in *vulnerability*, airport security can become much easier or much more difficult depending on where the airport is situated. Not just terrain topography, but what's adjacent to airports as to buildings, people, and everyday life. The ease or difficulty of airport security also depends on anything from the planning and design of parking, concessions, ticketing, interior layouts, runways, other infrastructure, and airport processes directly or indirectly supporting aviation. There's huge variability—often based on when, why, and how an airport was initially conceived—on how much airport security is a significant factor in planning and design or just an afterthought. The challenges of security as afterthought usually become salient after significant attempts to harm airport security and well-publicized attempts elsewhere to harm various transportation modalities and other public and even private venues.

Impediments to security-appropriate airport planning and design potentially include extra costs, trade-offs of security versus traveler comfort and flight efficiency, and comparative values as to human life. These can be anticipated and often resolved, if there's a will to concurrently manage multiple concerns. What can't always be anticipated are specific changes impacting the airport, for example, social and cultural changes from massive ingress and egress of populations; significant changes to the ratio of commercial and residential populations and the infrastructures of urbanization and de-urbanization; and new technologies that pose new security challenges including voiding what once was protection afforded by physical and natural barriers. Even the long-studied challenge of aviation-related noise pollution can have security impact through inadequate systemic analysis of trade-offs in comparative mitigation.

Surveillance and reconnaissance adjacent to and over the airport. Human assets and technical assets need to be deployed and employed to deter and minimize attacks from off-airport launched missiles; radiological and explosive weapons planted on adjacent roadways and incoming vehicles; off-airport staging areas for human attacks usually mediated with weapons; fixed wing, rotary, and unmanned aerial systems threatening aircraft on the ground or as they approach take-off or landing, as well as infrastructure, personnel, and travelers; even the surveillance and reconnaissance capabilities of those seeking to harm security. Another important technique is placing restrictions on adjacent ground areas and establishing non-fly restriction zones, as well as regulating and enforcing what can be in the air and the minimum distances between airborne aircraft. A more recent *threat* is that of unmanned aerial systems (UAS), for example, drones, as to damaging engines or other infrastructural aspects of aircraft as well as aircraft crew and passengers, and airport staff and travelers through direct kinetic impact. UAS threat also can lead to security decisions to shut down flight operations and to induce formal and informal changes in the flight paths of other aircraft. Problems in countering the UAS *threat* include devising techniques that do not pose an unacceptable risk to non-threatening people, things, and processes. The UAS *threat* also can constitute a platform for weapons employment and hostile cyber acts (see *Cyber security* later). UAS military and civilian proliferation is in such a drastic state of flux that all facets of airport infrastructure and operations are continuously being re-evaluated as to safety and security.

"Hardening" of aircraft. More against threats from terrorism and emotional and mental dispositions and disorder via decreasing *vulnerability*, attempts continue to modify and create aircraft designs, structures, materiel, and technologies to withstand explosions, crashes, and human violent behavior (see *Cyber security* later). Initiatives focus on increasing the difficulty of opening and going through cockpit doors, negotiating secondary flight deck barriers, otherwise accessing the flight deck, and preventing or distorting cabin-cockpit-air traffic control communications. In addition, there continue to be upgrades in the fidelity, real-time transmissibility, and crashworthiness of audio, video, and technical data recording. More controversial have been the utility of on-board armed security like air marshals and law enforcement; self-defense training and/or arming flight crew and attendants; and standardized, scenario-dependent education and training of passengers for scenario-dependent engagement. This latter would "aviation-ize" the common alternatives for an on-the-ground mass shooting, for example, run, hide, or fight might become do nothing, crouch in your seat, or variously engage.

Surveillance and reconnaissance at the airport. The two main kinds of capability are screening people and screening things for threat indicators. Both have problems with unacceptably high combinations of true and false positives (with positives indicating an actionable threat) and negatives (with negatives not indicating such a threat) (cf. [Harcourt, 2007](#)). Inadequate attempts to identify accurate error rates for screening occur because of policy decisions not to engage in applied research, the use of lab as opposed to field research, and field research grossly unrealistic to the environment of a daily operational environment. Also, error rates are often partially reported in a manner occluding significant shortfalls. For example, one can easily have a 100% accurate true positive rate by allowing a huge false positive rate—namely, identifying everyone as an actionable threat. Also, when applied research is accomplished, statistical analyses often are inadequate. One example of this is not allowing for the often very low base rates of attempts to harm security. Another is not explicitly making assumptions as to whether one assumes to be sampling different facets of the same population or a series of different population. Finally, statistics are chosen and interpreted without actual balancing of the priorities for large effect sizes and the likelihood of identifying true positives or true negatives. This has an impact on human, other animal, and technical screening capabilities from observation, smelling, frisking, interviewing, and various technical analytic backups—namely, algorithms programmed to spot threat indicators worthy of security action. A so far insurmountable challenge is that threat indicators can be exhibited by non-threatening people and things, no threat indicators from an actual *threat*. Finally, a common recommendation is to employ a "weak" profiling—combinations of universal screening for certain threat indicators and random sampling for other indicators.

Screening people. Whether for aircraft crew, airline personnel, airport staff, or travelers, this should begin with various data mining approaches beginning before anyone arrives at the airport. Data mining problems include incomplete, ambiguous, and partially contradictory repositories of information suggesting threat indicators; the degree of direct, indirect, and inferential linkages between threat indicators and harming security; and the transience of reliable and valid linkages ([Bloom, 2009](#)).

Once at the airport, screening entails the use of various verbal and nonverbal criteria, almost all with suspect linkage with threat. The shortfall is founded on the applied research problems described earlier. Some recent work on differential verbal response while engaged in a question answer dialogue with a trained interlocutor may show some operational promise. It is unfortunate that the quite significant body of applied psychological research on terrorism, non-political crime, and emotional and mental dispositions and disorders does not support strict use of profiles without significant error rates. It's a political decision how acceptable an estimated false positive error rate can be to secure an estimated true positive rate. Even for biometrics and facial recognition technologies, there are issues. Biometric data often facilitate validating an individual's identity, but not their intent. Although iterations of facial recognition technologies continue to resolve the challenges of ambient lighting and shading, body movement, and micro-facial expressions, the identity-intent distinction applies. However, biometrics—including facial recognition, DNA sampling, and recognition of palm prints, hand geometry, iris and retina, and odor/scent—can function as deterrent and minimization of *threat* and provide useful data for investigations and analyses after security has been harmed. And yet their value can be mitigated through having access to incomplete, poorly categorized and constructed, and difficult to access comparative data-bases.

Screening things. Here the two most highly salient *threats* bear on baggage (both carry-on and checked) and cargo.

As to baggage, whatever combinations of human, other animal, or technical approaches are employed, one problem is matching the physical and psychological capabilities of the screener with the telling physical characteristics of the baggage (and cargo). It's

fairly easy for the more sophisticated among those who intend to harm security to learn these capabilities and successfully plan by creating a mismatch with characteristics of weapons, weapon's components, explosives, chemical, biological, and radiological agents, and so forth (Press, 2008).

As to cargo, a salient issue is the often long and discontinuous chain of custody (admittedly, something that could occur with baggage as well) from point of production to final destination. Much as upscale gambling establishments are often a font of inspiration for profilers of proscribed behaviors, so are those who seek to impede multinational illicit trafficking in drugs, weapons, other commodities, and people. A recent prosecution of a famous drug trafficker yielded deceptive techniques to move cocaine varying from cans of chili to shoe boxes to tanker ships.

Cyber security. Cyber acts defined as comprising the production, storing and transmitting of information via overlapping entities of computers, information technology, and virtual reality pose an increasing threat to airport and aviation security, but also to those who seek to harm it (Zaccaro, 2016). As with all yoked enterprises of crime/counter-crime, spy/counter-spy, there's a continuing escalation in both how to reinforce security and harm it. At issue are accessing, transmitting, modifying, and impeding information with and without appropriate authorization. These can be employed to harm people, things, and processes and to steal financial assets otherwise available for security. There seems to be catastrophizing as to a comprehensive identification of threats and vulnerabilities, especially as to taking control of airborne aircraft and planting hardware/software elements to induce disaster. The two sources of *threat* and *vulnerability* in cyber security are technological and human. The human—especially the insider *threat*—is often discounted or viewed as a secondary concern. Other issues of concern include human and technical information accuracy, adequacy, fidelity, and timeliness within, between, and among air traffic management, aircraft, and airport personnel. Shortfalls can result in crises, critical incidents, and unsatisfactory management of the same.

Airport Security: The Future

Optimal testing of layers of security should increasingly comprise offensive and defensive perspectives—often called red team/blue team exercises. Layers of security may vary in looking predictable and unpredictable depending on intelligence about expectations of the *threat* and *threat-vulnerability* matches prioritized for probability of occurrence and likely impact. Significant traditional, mass, and social media descriptions and reporting on aviation and airport disasters are likely to continue to increase the attractiveness of flight as target by terrorists and those with emotional and mental dispositions and disorders, less so with non-political criminals. Thus, global, regional, national, and local policies about the communicating harms to security need to be re-assessed balancing need-to-know and need-not-to-be-harmed. Applied research needs to be even more sensitive to tradeoffs in assumptions about the realism of field experiments and about statistical assumptions used to make inferences—common labels for the latter options include Bayesian, fiduciary, frequentist, and (decision) theoretical. And the cyber security challenge still has too many unknown unknowns and—along with more efficacious intelligence activities and information operations—remains the highest priority for more resources.

Ironically, with all the technological challenges, airport security is ultimately a human problem. The irony stems from increasing observations that human nature itself may be changing in a globalizing, cyberworld (Zuboff, 2019). We don't know what this means for airport security—as to future threats, vulnerabilities, and risks. But we will speculate that many capable men and women will take up the challenge—to protect the flying public, to exploit it, and to destroy it.

Introduction

Alcohol Impairment and Blood Alcohol Concentration (BAC)

Laboratory studies indicate that impairment in critical driving functions begins at low blood alcohol concentrations (BAC). Most subjects in laboratory studies are significantly impaired regarding visual acuity, vigilance, drowsiness, psychomotor skills, and information processing by the time they reach .05 g/dL BAC compared to their performance at .00 g/dL BAC. A review of the scientific literature on the impairment of driving-related skills at low BACs based on laboratory testing of alcohol-dosed subjects documented that impairment of driving-related skills starts at very low BACs, for some as low as .02 g/dL BAC. A review of 177 studies ([Moskowitz and Robinson, 1988](#)) clearly documented significant impairment at .05 g/dL BAC and higher, and a review of 112 more recent studies in 2000 provided even stronger evidence of impairment at .05 g/dL BAC ([Moskowitz and Fiorentino, 2000](#)). Together, these two reviews have summarized the findings of nearly 300 studies of impairment at low-BAC levels, and the findings are remarkably consistent.

Relative Risk of Being Involved in a Crash by BAC

It has been recognized that alcohol is a factor in crashes since the beginning of the 20th century. However, the mere association of alcohol with crash involvement does not demonstrate a causal influence unless all other relevant factors can be eliminated. More direct evidence of a causal relationship is provided by demonstrating that crash probability is directly related to the amount of

alcohol in the driver's body. *Relative risk* studies attempt to refine the influence of alcohol on crashes by comparing drivers in crashes with similar drivers using the road at the times and places where crashes have occurred. Such studies are titled "case-control" investigations because, for each crash-involved driver (case), one or more non-crash-involved drivers (control) are selected for comparison. The key to such studies is to ensure that the comparison driver is selected so that the only distinction between the two is the involvement in a crash. This is achieved by going to the same location where the crash occurred at the same time of day on the same day of the week and randomly selecting comparison drivers (non-crash-involved drivers) operating vehicles in the same direction on the road as the crash-involved driver. Although nine studies of this type have been conducted over the last 80 years, in practice this level of control has rarely been achieved.

The most influential of the case-control studies was conducted by Robert Borkenstein in Grand Rapids, Michigan, in which 5985 crash-involved drivers were compared with 7590 control drivers (Borkenstein et al., 1974). Between July 1952 and July 1953, research staff members traveled to the sites of crashes occurring between 6:30 p.m. and 10:30 p.m. on Monday through Saturday to collect breath samples from crash-involved drivers. Later, they collected data on four comparison drivers at each site where crashes had occurred in the previous 3 years, not the same sites as the locations at which they collected the crash driver cases. Thus, the study was not strictly a case-control study because the comparison cases were not matched to the drivers in the crash cases. Rather, comparison drivers were matched to drivers in crashes randomly sampled from police accident reports occurring during the previous 3 years. Further, no correction was made for drivers who refused to provide breath tests. Finally, the group of crash-involved drivers who were compared to the control group was modified to represent drivers judged to be "at fault" by a process of combining those in single-vehicle crashes with half of those in two-car crashes. Despite these limitations, the Grand Rapids study became the gold standard for estimating the relative risk of involvement in an alcohol-related crash based on the driver's BAC.

More recently, other case-control studies have been conducted in Huntsville, Alabama, in 1977 involving 650 drivers in injury crashes and in Adelaide, Australia, in 1980 involving 299 drivers in injury crashes. Both of those studies, like the earlier ones just described, developed relative risk curves, which showed rapid rises at BACs higher than .05 g/dL.

Because other variables as age, gender, and quantity and frequency of drinking can vary between the drivers in crashes and the comparison drivers, it is necessary to compensate for these differences by the use of covariates in computing the risk curves. A study in 2005 collected information on a substantial set of demographic variables including items, such as marital status, education, ethnicity, employment status, and vehicle type as well as age and gender for use in correcting the differences between the crash and comparison populations of drivers (Blomberg et al., 2005). Logistic regression analyses were used to tease out variables which were most important in distinguishing crash and control drivers and those that proved to be significant were used as covariates in adjusting the risk curves. The significance of adjusting those differences in calculating the risk curve is shown in Fig. 1.

That study found a statistically significant relative risk of a crash at BAC $\geq .04$ g/dL and increasing exponentially at BACs $\geq .10$ g/dL and higher. There is no evidence that lower levels of alcohol consumption actually reduce or increase the crash risk (e.g., BACs less than .04 g/dL).

A recent case-control study was conducted in Virginia Beach, Virginia, USA, during a 20 month period in 2010–11 to estimate the risk of crashes involving drivers using drugs, alcohol, or both (Compton and Berning, 2015). Biological measures were obtained on more than 3000 crash drivers at the scenes of the crashes, and 6000 control (comparison) drivers. Control drivers were recruited 1 week after the crashes at the same time, day of week, location, and direction of travel as the crash-involved drivers. Data included over 10,000 breath samples, 9,000 oral fluid samples, and 1,800 blood samples. Oral fluid and blood samples were confirmed for the presence of alcohol and drugs. The crash risk associated with alcohol and other drugs was estimated using odds ratios that indicate the probability of a crash occurring over the probability that such an event does not occur. For example, if a variable, such as alcohol

Figure 1 Relative risk of a crash by BAC with covariates and without covariates. Source: Blomberg, R.D., Peck, R.C., Moskowitz, H., Burns, M., Fiorentino, D., 2005. Crash risk of alcohol involved driving: a case-control study, final report to the National Highway Traffic Safety Administration. Dunlap and Associates, Inc., Stamford, CT.

and/or drugs is not associated with a crash, then the odds ratio for that variable will be 1.00. A higher or lower number indicates a relationship between the probability of a crash occurring and the presence of that variable. Confidence intervals (CIs) of an odds ratio indicate the range in which the true value lies—with 95% confidence. Alcohol was the largest contributor to crash risk. The crash risk estimates for alcohol indicated drivers with breath alcohol concentrations of .05 g/210 L were 2.05 times more likely to crash than drivers with BACs=.00 (no alcohol). For drivers with BACs of .08 g/210 L, the relative risk of crashing was 3.98 times that of drivers with .00 BACs.

Setting BAC Limits for Driving

A general review of studies of the effect of lowering the BAC limit in Australia, Europe, and the United States was conducted in 2006 and concluded that lowering the BAC limit to .05 would be likely to reduce alcohol-related crashes in the United States. A study in 1994 found that lowering the BAC limit from .08 to .05 g/dL in New South Wales, Australia, significantly reduced fatal crashes on Saturday by 13%. Another Australian study conducted in 1995 employed a rigorous time-series analysis of random breath testing (RBT) and .05 BAC laws in Australia, controlling for many factors including seasonal effects, weather, economic trends, road use, alcohol consumption, and day of the week. Although the primary focus of the Australian study was the impact of RBT, the findings on the effect of .05 BAC laws were also significant.

There is a strong case for setting a .05 BAC limit for driving. Laboratory and test track research shows that the vast majority of drivers, even experienced drinkers who typically reach BACs of .15 or greater, are impaired at .05 BAC and higher with regard to critical driving tasks. There are significant decrements in performance in areas, such as braking, steering, lane changing, judgment, and divided attention at .05 BAC. Some studies report that performance decrements in some of these tasks are as high as 30%–50% at .05 BAC. In addition, as shown in the previous section, the risk of being involved in a crash increases significantly at .05 BAC. The risk of being involved in a crash increases at each positive BAC level, but rises very rapidly after a driver reaches or exceeds .05 BAC compared to drivers with no alcohol in their blood systems.

Lowering the illegal per se limit to .05 BAC is a proven effective countermeasure, which has reduced alcohol-related traffic fatalities in several countries, most notably, Australia. While studies in Europe and Australia, each use a different methodology to evaluate these effects, the evidence is consistent and persuasive that fatal and injury crashes involving drinking drivers decrease on the order of at least 5%–8% and up to 18% after a country lowers their illegal BAC limit from .08 to .05 BAC. A 2017 meta-analysis of international studies on lowering the BAC limit in general found an 11.1% decline in fatal alcohol-related crashes from lowering the BAC to .05 or lower (Fell and Scherer, 2017). The study estimated that 1790 lives would be saved each year, if all states in the United States adopted a .05 BAC limit.

Zero-Tolerance Laws for Underage Drivers

By 1988, all states in the United States had enacted minimum legal drinking age (MLDA) laws making it illegal for those younger than 21 to purchase or possess alcohol. This provided a basis for implementing a zero BAC limit for drivers aged 20 and younger (generally defined as a BAC of .02 or greater). These zero-tolerance laws for youth have proven effective in reducing fatal crashes involving underage drinking drivers. A meta-analysis conducted in 2001 of the studies of zero-tolerance laws found reductions of 9%–24% in fatal crashes (Shults et al., 2001).

Alcohol Regulation

Minimum Legal Drinking Age (MLDA) Laws

Stimulated by the scientific and safety advocate support for limiting underage access to alcohol, a basic set of at least 20 laws directed at (1) control of furnishing and selling alcohol to youth, (2) possession and consumption of alcohol by youth, and (3) prevention of impaired driving by those aged 20 and younger have been adopted in the United States over the last 3 decades in many of the 50 states and the District of Columbia (DC). Evidence exists that such laws can influence underage alcohol-related traffic fatalities. From 1988—when all states had enacted MLDA-21 legislation—to 1995, alcohol-related traffic fatalities for youth aged 15–20 declined from 4187 to 2212, a 47% decrease, with wide variability in these declines between states.

Numerous studies, including a comprehensive review of literature from 1960 to 1999 (Wagenaar and Toomey, 2002), uniformly showed that increasing the minimum drinking age significantly decreased self-reported drinking by young people, the number of fatal traffic crashes, and the number of arrests for driving under the influence (DUI) involving youths aged 20 and younger. In 2001, a meta-analysis of 33 studies of the MLDA was conducted. That study showed that the MLDA resulted in changes of 10%–16% in fatal crashes: increasing fatal crashes, if the MLDA was lowered, and decreasing fatal crashes, if it was raised. In 2006, a study found that when New Zealand lowered its drinking age from 20 to 18, crash injuries among 15–19-year-olds increased.

Recent legal research involving the use of the Alcohol Policy Information System (APIS) developed under a grant from the National Institute on Alcohol Abuse and Alcoholism (NIAAA) has indicated that there are at least 20 MLDA-21 laws that have been adopted at the state level in the United States. **Table 1** contains a brief summary of those 20 laws; in parentheses and in bold is the number of states (including DC) that have currently adopted each law (Fell et al., 2015).

Table 1 Minimum legal drinking age 21 (MLDA-21) law components and descriptions

MLDA-21 law components	Description
Core laws that apply to youth	
1. Possession	Illegal for youth under age 21 to possess alcohol (50 states + DC)
2. Purchase	Illegal for youth under age 21 to purchase or attempt to purchase alcohol (47 states + DC)
Expanded laws that apply to youth	
3. Consumption	Illegal for youth under age 21 to consume alcohol (34 states + DC)
4. Internal possession	Evidence of possession and consumption via a BAC test (9 states)
5. Use and lose	Alcohol citation for youth under age 21 results in drivers' license suspension (39 states + DC)
6. Use of fake identification	Fake ID minor—illegal for youth under age 21 to use a fake identification to purchase alcohol (50 states + DC)
Apply to youth driving	
7. Zero tolerance	ZT—illegal for a driver under age 21 to have any alcohol in their system when driving (50 states + DC)
8. Graduated driver licensing with night restrictions	GDL—youth with intermediate or provisional license prohibited from driving without an adult in the vehicle past a certain hour at night (50 states + DC)
Apply to providers	
9. Furnishing or selling	Illegal to furnish or sell alcohol to a youth under age 21 (50 states + DC)
10. Age of on-premise servers	Minimum age 21 set for selling/serving alcohol (13 states)
11. Age of on-premise bartenders	Minimum age 21 for bartenders (23 states + DC)
12. Age of off-premise sellers	Minimum age 21 set for selling/serving alcohol (23 states)
13. Keg registration	Identification number for beer keg and purchaser required (30 states + DC)
14. Responsible beverage service training	RBS—responsible beverage training mandatory or voluntary (37 states + DC)
15. Retailer support provisions for fake identification	Fake ID retailer—provisions to assist retailers in avoiding sales to youth under age 21 (45 states)
16. Social host prohibition	SHP—prohibits social hosting of underage drinking parties (28 states)
17. Dram shop liability	Action against commercial provider of alcohol (44 states + DC)
18. Social host civil liability	Action against non-commercial (private) provider of alcohol (33 states)
Apply to manufacturers or suppliers of fake identification	
19. Transfer/production of fake identification	Fake ID supplier—prohibits manufacturing and/or supplying fake identification to youth for the purposes of buying alcohol (24 states)
Apply to states concerning control of alcohol distribution	
20. State control of alcohol sales	State control—a state-run retail distribution system of alcoholic beverages (i.e., beer, wine spirits) (11 states)

Source: *Fell et al., 2015*

The 20 MLDA-21 laws used in a 2016 study were scored in a prior study for their strengths and weaknesses based on (1) the sanctions enacted for violating the law, (2) any exceptions or exemptions affecting the application and enforcement of the law, and (3) any provisions that could affect the law or its enforcement negatively or positively. The strength scores of these laws were used to assess the impact of 20 MLDA-21 laws on underage alcohol-related outcomes, including underage drinking-and-driving fatal crashes. The nine MLDA laws associated with significant decreases in fatal crash ratios of underage drinking drivers were: possession of alcohol (−7.7%), purchase of alcohol (−4.2%), use alcohol and lose your license (−7.9%), zero tolerance .02 BAC limit for underage drivers (−2.9%), age of bartender ≥21 (−4.1%), state responsible beverage service program (−3.8%), fake identification support provisions for retailers (−11.9%), dram shop liability (−2.5%), and social host civil liability (−1.7%) (*Fell et al., 2016*).

The nine laws are estimated to be currently saving approximately 1135 lives annually in the United States (*Fig. 2*). The researchers estimated that if all states adopted them, an additional 210 lives could be saved each year. Only five states have all nine effective laws: California, Colorado, New Mexico, Utah, and Wyoming.

Driving Regulation

Graduated Driver Licensing for Young Drivers

Research has shown that the first few months of licensure for young novice drivers entail the highest crash risk. To address this issue, many countries have adopted graduated driver licensing (GDL) laws that require a staged progression to full license privileges. GDL laws generally require three-staged licensing for novice drivers: (1) a learner's permit period—practice driving with a licensed driver, (2) an intermediate or provisional stage—drive solo only under certain conditions (e.g., restricts late-night driving and limits teen passengers); and (3) a full license with no restrictions (minimum age of 18 in most countries). The young driver must meet certain requirements to “graduate” to each stage. Nighttime restrictions have been found to reduce novice driver involvements in nighttime fatal crashes by an estimated 10% and young drinking drivers in nighttime fatal crashes by 13%. Passenger restrictions have been found to reduce novice driver involvements in fatal crashes with teen passengers by an estimated 9%. These results confirm the effectiveness of these provisions in GDL systems.

Figure 2 Estimated lives saved by nine MLDA-21 laws. Source: Fell, J.C., Scherer, M., Thomas, S., Voas, R.B., 2016. Assessing the impact of twenty underage drinking laws. *J. Stud. Alcohol Drugs* 77, 249–260.

Drinking and Driving Legislation

Impaired-Driving Laws

Over the last quarter century, much of the research in traffic safety has focused on the evaluation of proposed new laws and the development of tools for use by the police and courts in the enforcement of DUI laws. The most significant laws are listed in [Table 2](#), and recent research on key DUI laws is described in the following sections.

Administrative License Revocation/Suspension (ALR/ALS)

ALR/ALS is a proven effective sanction. ALR laws, which provide that the license of a driver with a BAC at or over the illegal limit is subject to an immediate driver's license suspension by the state or country agency in charge of driver licensing and motor vehicles, are the most widely applied example of a traffic law where the sanction rapidly follows the offense. The power of ALR laws has generally been attributed to how swiftly and how certain the sanction is applied. This licensing control measure also rapidly removes a high-risk driver from the public roadways. Several large national studies have demonstrated that the presence of an ALR law is associated with a reduction in alcohol-related crashes.

Table 2 Key DUI laws

DUI law	Description
Impaired-driving law	The traditional law against drinking and driving that depends on the officer presenting observations of the suspect's behavior that demonstrates the driver was under the influence of alcohol. It does not depend on the presentation of a BAC test result, but if the BAC level is available; it becomes presumptive evidence of intoxication.
Per se law	Operating a vehicle with a BAC at or higher than a specified illegal limit. When a BAC level is not available, the prosecution must be conducted under the impaired-driving law.
Zero-tolerance law (a "status" law based on age)	Based on the minimum legal drinking age law, the zero-tolerance law makes it an offense for a person younger than age 21 to operate a motor vehicle with any measurable amount of alcohol in their bodies; generally specified as a BAC of .02 or greater.
Implied-consent law	Establishes that, by accepting a driver's license, a driver agrees to submit to a chemical test if an officer has probable cause to make an arrest for impaired driving. In the event of a refusal, most statutes provide that no test will be given, but the suspect's license will be suspended. Alternatively, the officer can seek a warrant to require a blood test.
Administrative license revocation law	Provides that a DUI suspect whose chemical test result is higher than the legal limit (currently .08) is subject to an immediate license suspension. A provision must be made for a hearing, if requested by the offender.
High BAC laws	Provides for increased sanctions for a convicted DUI offender whose BAC level is .15 or greater.
Test refusal law	Provides for increased sanctions for DUI suspects who refuse the chemical test.
Anti-consumption, open container law	Prohibits consumption of alcohol by the driver while in charge of a vehicle or more commonly prohibits an open alcohol container in the passenger compartment of a vehicle. Passengers in commercial vehicles, such as buses, are normally exempted.

Mandating Alcohol Ignition Interlocks for all Convicted DUI Offenders

Installing alcohol ignition interlocks has been shown to have both a general deterrent and specific deterrent factor. Alcohol ignition interlocks require a negative breath test to start a vehicle's engine, and some countries have mandated some form of interlock law for drivers convicted of driving while intoxicated (DWI). A study in the United States showed that all-offender laws were associated with 16% fewer drivers with .08+ BAC involved in fatal crashes, compared to no interlock law (Teoh et al., 2018). Repeat-offender interlock laws were associated with a nonsignificant 3% reduction in impaired drivers, compared to no law. Repeat and high-BAC interlock laws were associated with an 8% reduction in impaired drivers in fatal crashes, compared to no law. Laws mandating alcohol ignition interlocks, especially those covering all offenders, are an effective impaired driving countermeasure that reduces the number of impaired drivers in fatal crashes.

Enforcement of Impaired Driving Laws

The effectiveness of traffic laws related to impaired driving depends on deterring vehicle operators from driving after drinking. The principal factor in creating deterrence is how effectively the laws are enforced. Classical deterrence theory is a psychological model designed to explain the influence of punishment on personal behavior. It holds that three factors—risk of detection, severity of the sanction, and the speed with which the sanction is applied—determine the response to laws. Deterrence is the perception of each of the three factors—rather than the actual risk of detection, the sanction severity, and sanction celerity—that controls the behavior of offenders. The basic theoretical concept has been demonstrated in many evaluations of traffic safety programs conducted in the last half century (Ross, 1973).

Sobriety Checkpoints and Random Breath Testing (RBT)

Sobriety checkpoints provide the US police departments with the closest approximation to the highly successful random breath testing (RBT) enforcement procedure used in Australia, Sweden, and other countries. RBT, as implemented in Australia, allows officers to stop any vehicle on the road at random and to take a breath test from the driver. Operators with BACs greater than .05, which is the legal limit, are transported to the police station for an evidential test. In contrast, in the United States, vehicles can only be stopped at random at specially designed "checkpoints," and the drivers cannot be required to take a breath test. Rather, the officer must conduct an interview to determine whether the driver is impaired, and if there is evidence of impairment, the officer must require the driver to perform a set of field sobriety tests to establish impairment before transporting the offender to the police station.

In a time-series analysis of four Australian states, researchers found that RBT was twice as effective as "selective" checkpoints similar to those conducted in the United States. Another study found that in Queensland, Australia, RBT resulted in a 35% reduction in fatal crashes, compared with 15% for checkpoints. The researchers estimated that every increase of 1000 in the daily RBT testing rate corresponded to a decline of 6% in all serious crashes and 19% in single-vehicle nighttime crashes. Moreover, analyses revealed a measurable continuing deterrent effect of RBT on the motorist population after the program had been in place for 10 years. On the other hand, a review of studies on the effectiveness of sobriety checkpoints in Thailand showed mixed results (some showed effectiveness, others showed no effects).

Studies of the US sobriety checkpoint procedure found that they are associated with significant decreases in alcohol-related crashes. Reviews of checkpoint programs have reported reductions of 17%–75% in alcohol-related fatalities. Two related meta-analyses studies of 15 US checkpoint programs occurring between 1985 and 1999 found that the median reduction in crashes associated with checkpoints was 20% (Elder et al., 2002). A cost-benefit study of sobriety checkpoints indicated that, for every

\$1 invested in the checkpoint strategy, the community conducting the checkpoint saved \$6. In a recent report published by the Transportation Research Board of the National Academies of Science, Engineering and Medicine, the lessons from other nations indicate that frequent and sustained use of sobriety checkpoints could save up to 3000 lives annually, if used in the United States ([Transportation Research Board, 2010](#)). If passive alcohol sensors (PAS) are used at sobriety checkpoints, this could simulate the effects of RBT.

A benefit of checkpoint operations that has not been fully evaluated is the suppression of crime beyond impaired driving. In 2003, the Fresno, California, Police Department increased impaired driving enforcement from 1 or 2 operations per year between 1998 and 2002, to 32 in 2003 and almost 130 in 2010. Between 2003 and 2011, not only were alcohol-related crashes reduced by 17%, but also burglary rates and motor vehicle theft rates per capita declined by 17% and 32%, respectively.

Preventing Impaired Driving Offenders From Repeating

License suspension was once the most effective single DUI sanction. However, recent evaluation studies have found remedial interventions (treatment and educational programs) to be more effective than traditional punitive sanctions, such as jail terms and fines when combined with license restriction, for reducing recidivism and alcohol-related crashes. A meta-analysis conducted in 1995 of 215 evaluations of drink-driving remediation (treatment) programs concluded that the best designed studies indicated that treatment can produce an additional 7%–9% reduction in drink-driving recidivism and alcohol-related crashes when compared with control groups that largely received license restrictions only (sometimes more severe than for the treatment groups) ([Wells-Parker et al., 1995](#)).

DUI/Drug Courts

Based upon the effectiveness of these drug courts, DUI courts have been established to provide intensive supervision of offenders by judges and other court officials who closely monitor compliance with court-ordered sanctions coupled with treatment. DUI courts generally involve frequent interaction between the offender and the DUI court judge, intensive supervision by probation officers, an appropriate level of treatment, random alcohol and other drug testing, community service, lifestyle changes, positive reinforcement

for successful performance in the program, and jail time for noncompliance. Mostly nonviolent offenders who have had two or more prior DUI convictions are assigned to a DUI court, if one exists in the jurisdiction (not all communities or states have DUI courts). Several studies have reported favorable results for DUI/drug courts; however, additional evaluation is required, particularly in the area of cost-effectiveness because of the heavy use of court resources.

Screening and Brief Interventions

When drink-driving prevention fails, many drivers become involved in crashes and wind up in hospital emergency rooms or regional trauma centers. This provides an opportunity outside the criminal justice system for the private health care system to intervene with high-risk drivers. The trauma of being involved in a crash is viewed as providing a “teachable moment,” when individuals may be open to undertaking a behavioral change that will reduce their risk of future crashes and injuries. Research suggests that 30%–50% of injured, crash-involved drivers admitted to emergency departments or trauma centers have BAC levels higher than the legal limit for driving. Some of these offenders may receive a treatment intervention because of a DUI arrest; however, many are not charged because they are taken to the hospital before police officers have an opportunity to examine them for impairment. Furthermore, hospital staff rarely notifies the police when they receive a high-BAC driver. When screened for alcohol use disorders, an estimated 27% of injured patients admitted to the emergency department or a trauma center test positive for alcohol abuse or dependence, indicating a large number of people entering emergency rooms are potential DUI offenders. Thus, emergency rooms and trauma centers have an important opportunity to intervene with high-risk individuals who need treatment for alcohol problems—problems that may well lead to impaired driving and alcohol-related crashes in the future. Most importantly, brief interventions effectively improve consequences related to driving, such as moving traffic violations, drink-driving violations, motor-vehicle crash involvement, crash sustained injuries, and motor-vehicle fatalities.

Vehicle Sanction Laws

Aside from the traditional license suspension sanction, several laws and programs have been developed that prevent the offender from driving. These laws provide for seizing and impounding, immobilizing, or forfeiting the offender’s vehicle, and programs for interlock-equipped vehicles prevent a drinking driver from starting a vehicle. Overall, existing studies suggest that impoundment is an effective method of reducing the recidivism of DUI and driving-while-suspended (DWS) offenders. For vehicle impoundment to be effective, the vehicle must be impounded when the offender is arrested, and a procedure must be devised to deal with nonoffender owners.

Alcohol Monitoring

An alternative to controlling the driving of DUI offenders is to control their drinking. Judges frequently admonish offenders to remain abstinent while on probation, but unless a program exists that monitors the BAC, this action has little force other than allowing the judge to impose more severe penalties, if the offender returns to court intoxicated during the probation period. In the past, offender abstinence has been monitored in several ways. Some courts have implemented closely supervised Antabuse administration, which is drug that makes the offender sick, if they consume alcohol. Others have implemented intensive supervision programs in which probation officers make surprise visits to the homes of offenders and conduct breath tests. As noted, DUI/drug courts generally provide for intensive monitoring of abstinence. Such systems are labor intensive and expensive for the courts. In the last couple of decades, innovative technological methods for collecting BAC data have received considerable attention. One of these systems, electronically supervised, home-confinement programs, has been used for some time. This program involves telephone-monitored electronic random breath testing (RBT) systems that allow frequent monitoring of the BAC level while the offender is at home.

The South Dakota 24/7 Sobriety Program is a sobriety monitoring program aimed toward repeat DUI offenders, first DUI offenders with very high BACs, and similar offenders who have had repeated convictions related to alcohol abuse. Offenders report to the Sheriff’s Office twice a day (at about 7 a.m. and 7 p.m.) for alcohol breath testing. If the offenders have any positive BACs or they miss a scheduled test, they go to jail for 12–36 h. South Dakota adopted legislation in 2007 that established the 24/7 program statewide. The program is now operating in 60 of the 66 counties in South Dakota and has been implemented in North Dakota, Wyoming, and other states. An independent evaluation of the South Dakota 24/7 program in 2013 showed a 12% reduction in repeat DUI arrests and a 9% reduction in domestic violence arrests associated with the adoption of the 24/7 program (Kilmer et al., 2013).

More direct transdermal-monitoring systems that are worn on the body and monitor the BAC level 24 h a day/7 days a week are used by the judicial system. Two devices have been studied—the SCRAM ankle bracelet and the WristAS, which is about the size of a large wristwatch. The SCRAM incorporates a system for detecting circumvention. Although laboratory evidence indicates that SCRAM is reasonably accurate in detecting a significant BAC, no adequate evaluation of the SCRAM unit has been conducted with DUI offenders to determine its effectiveness in maintaining abstinence.

A method for monitoring drinking that is just emerging in the United States but is more widely used in Europe is to analyze the biomarkers in blood, urine, or hair that result from consumption of alcohol. Although alcohol is cleared relatively rapidly from the body, usually even after heavy drinking within 8–12 h, alcohol biomarkers persist in circulation in hair and in urine long after alcohol has fallen to zero in the blood. These biomarkers provide a way to measure total consumption over an extended time span. Longer-lasting blood markers reflecting alcohol use, such as urinary ethylglucuronide (EtG), offer a window of detection of 36 h or more following drinking. Hair EtG is being used in Germany as a relicensing criterion for participants in the driver's license restitution processes following conviction for impaired driving. To be eligible for reinstatement, a person's hair EtG level must be below 3 pg/mg (picograms/milligram), which is known to reflect abstinence.

Alcohol Consumption

Generally, a country with a low rate of alcohol consumption per capita has a low alcohol involvement rate in fatal traffic crashes [e.g., Saudi Arabia (0.2 L of pure alcohol per capita), Turkey (2.4 L)]. However, that is not always the case as some countries with high alcohol consumption rates [e.g., Russia (14.5 L), Czech Republic (14.1 L), Australia (12.6 L), United Kingdom (12.0 L)] have low alcohol involvement rates in fatal crashes [e.g., Russia (5%, but most likely underreported), Czech Republic (8%), Australia (28%), United Kingdom (19%)]. The alcohol consumption rate in Sweden is 8.7 L of pure alcohol per capita and their fatal crash alcohol rate is 18%. In the United States, the alcohol consumption rate is 9.0 while the alcohol involvement rate in fatal crashes is 30%.

Countries that are highly urbanized and have adequate mass transit systems and other alternative transportation tend to have lower drinking and driving rates.

Alcohol Ignition Interlocks

The most parsimonious approach to the control of DUI offenders' impaired driving is the alcohol ignition interlock, which requires the driver to provide a breath sample when starting the car and at random times while driving. The units have four basic elements: (1) A breath-alcohol sensor that records the driver's BAC level and can be set to provide a warning, if any alcohol is detected and that will prevent starting the vehicle if the BAC is .03 or higher. (2) A rolling retest system that requires a new breath test every few minutes while driving to prevent someone else from starting the vehicle for a person who has been drinking. (3) A tamper-proof system for mounting the unit in the vehicle that is inspected every 30–60 days. (4) A data-logging system that records both the BAC tests and engine operation, thus ensuring that the offender is actually using the vehicle and not simply parking it while driving another vehicle. State-licensed service providers install the unit, inspect it regularly (generally, every 30–60 days), and provide a report on any attempt to circumvent the device to a court probation officer or a driver analyst at the department of motor vehicles. Such monitoring systems, with substantial consequences for tampering with the device, are essential for ensuring that offenders cannot drive the interlock-equipped vehicle while impaired. There is strong evidence that the recidivism of DUI offenders is substantially reduced while interlocks are on their vehicles. The offenders who install interlocks have 36%–90% lower DUI recidivism rates while the interlock is on their vehicles than similar DUI offenders who remain suspended ([Elder et al., 2011](#)). Once the interlock is removed, however, their recidivism rate does not differ from fully suspended offenders.

Three interlock laws were evaluated in 2018 by comparing alcohol-impaired passenger vehicle drivers involved in fatal crashes between 2001 and 2014 in the United States across state and time (Teoh et al., 2018). The exposure measure was the number of passenger vehicle drivers in fatal crashes that did not involve impaired drivers. Laws requiring interlocks for drivers convicted of DWI covered: (1) repeat offenders, (2) repeat offenders and high-BAC offenders, (3) all offenders, and (4) none. All offender laws were associated with 16% fewer drivers with .08+ BAC involved in fatal crashes, compared to no law. Repeat and high-BAC laws were associated with an 8% reduction in impaired drivers in fatal crashes, compared to no law. Laws mandating alcohol ignition interlocks, especially those covering all offenders, are an effective impaired driving countermeasure that reduces the number of impaired drivers in fatal crashes.

Conclusion

Alcohol-impaired driving is prevalent throughout most countries of the world. The key to controlling the problem is a systematic approach involving alcohol regulation, strong impaired driving laws, consistent, visible and frequent enforcement, and effective sanctions for DUI offenders. Success in the future involves passive alcohol detection systems in vehicles and the safety and feasibility of autonomous vehicles.

The Future

Driver Alcohol Detection System for Safety (DADSS) Program

A long-term development program was inaugurated by National Highway Traffic Safety Administration (NHTSA), automobile manufacturers, and Mothers Against Drunk Driving (MADD) to develop a system for all cars that can passively sense the BAC of the driver and prevent ignition of the vehicle's motor if the driver is over the BAC legal limit. The program is called "Driver Alcohol Detection System for Safety" (DADSS) and is currently being funded by NHTSA and most of the motor vehicle manufacturers (Zaouk et al., 2015). If such a vehicle can be produced, it would finally fulfill the objective enunciated 40 years ago—to build "Cars that Drunks Can't Drive." One of these monitors passively detects alcohol in the breath of the driver, making it unnecessary for the driver to blow into an interlock breath tube. Another developing technology measures BAC passively through the skin, providing a substitute for blowing into the interlock. These systems may have value as a method for activating a driver interlock system only when there is evidence of a drinking driver in the vehicle. Thus, the not-too-distant future offers the possibility of equipping all new vehicles with a system that would make impaired driving unlikely.

Autonomous Vehicles

Autonomous vehicles, if proven feasible and safe, could substantially change how we travel and could also eliminate drunk driving. While fully autonomous vehicles are not yet commercially available, the technology is developing rapidly and some computer-generated driving functions are already on public roads today. However, regulations are needed for enhancing safety and protecting the public interest. States will need to create stakeholder-working groups to oversee the development of state and local laws. One of the big questions will be: Can drunk drivers get home safely in autonomous vehicles?

Further Reading

NHTSA Alcohol and Highway Safety Reports

The first comprehensive report on alcohol and driving in the United States was issued in 1968 in response to a Congressional requirement when the National Highway Safety Bureau (now the NHTSA) was founded. This US Department of Transportation report summarized the fairly limited research in the traffic safety field and highlighted the role of “heavy drinkers” (alcoholics and problem drinkers) in the alcohol-related crash problem. It had a substantial influence on the safety community and was an important factor in the decision by Congress to appropriate funds for the Alcohol Safety Action Program (ASAP), the first National demonstration program on drinking and driving. A follow-up to the 1968 report, *Alcohol and Highway Safety: A Review of the State of Knowledge*, was published a decade later in 1978. The report covered three main areas: (1) it defined the alcohol-crash problem, (2) it addressed the alcohol-crash problem, and (3) it provided future directions for the alcohol-crash problem. The publication contained an extensive review of individual studies in localities throughout the United States. An important addition to the 1968 report was its presentation of a “health approach” as a part of the criminal justice system. This approach focused on screening people convicted of DWI offenses and referring them to treatment.

In 1985, an update of *Alcohol and Highway Safety* was published by NHTSA. This report built on the 1978 report and included the “most clearly important studies and findings for the period from January 1978 to December 1982.” This update contained the first discussion of vehicle and roadway engineering programs as methods for reducing impaired-driving crashes. It provided the first mention of alcohol ignition interlock systems. It also discussed the topic of exposure reduction (e.g., reduction in alcohol availability), the emergence of underage drinking as a potential issue in traffic safety, and the possible value of age 21 as the MLDA limit.

In 1989, the fourth in its series of *Alcohol and Highway Safety* reports was published. Influenced in part by the *Surgeon General’s Workshop on Drunk Driving* in 1989 that was held the year before, this update gave considerable attention to controls on the availability of alcohol, reporting that 28% of the countermeasure documents reviewed related to availability. This increased focus on laws and policies related to drinking, as distinct from impaired driving, and reflected the movement to close the gap between research on traffic safety and research on public health issues surrounding alcohol abuse that was stimulated by the *Surgeon General’s Workshop*.

The fifth in the series of *Alcohol and Highway Safety* reports was published in 2001. That report found evidence for the effectiveness of four types of legislation when enforced: ALR laws, reducing the legal BAC limit from .10 to .08 g/dL, raising the MLDA to 21, and zero-tolerance laws.

Other Comprehensive Reviews

Perhaps the most significant research update was published as a product of the *Surgeon General’s Workshop on Drunk Driving* conducted in 1988. The publication of the Workshop in 1989 consisted of a compendium of 15 papers provided by experts in traffic safety and in public health research. It covered a wide range of topics, including the pricing and availability of alcohol, alcohol advertising, and marketing, as well as traditional topics, such as the epidemiology of impaired driving, law enforcement, and DWI offender treatment programs. The significance of the publication was based on the participation in the workshop by researchers in both traffic safety and public health. Bringing together leaders in these two fields served to integrate public health activities directed at reducing the health risks presented by alcohol.

In 2001, the Transportation Research Board (TRB) Committee on Alcohol, Other Drugs, and Transportation produced a report on research needs and priorities. That document, like the *Surgeon General’s Workshop Report*, consisted of a compendium of individual papers. The presenters at the conference were required to respond to a set of evaluative questions; their responses were used to develop a list of alcohol research priorities.

The latest in the series of NHTSA *Alcohol and Highway Safety* reviews was published in 2006. Several smaller, independent reviews of the alcohol safety area have appeared in the last 2 decades, among them was the *Epidemiology and Consequences of Drinking and Driving* published in 2003. That report described the groups most at risk for the involvement in alcohol-related crashes, reporting that there are 80 million trips each year in which a driver exceeds the legal BAC limit (.08). Further, although alcohol-related fatal crashes decreased in the 1980s, there has been little reduction since the mid-1990s and even a slight increase between 2000 and 2003. A report funded in part by the World Health Organization (WHO), *Alcohol: No Ordinary Commodity Research and Public Policy*, provided a broad review of alcohol consumption, patterns of drinking, and policies directed at reducing high-risk drinking. The report also contains a chapter reviewing drinking-and-driving countermeasures.

In 2018, the National Academy of Sciences, Engineering and Medicine (NASEM) released the most comprehensive report on accelerating progress to reduce alcohol-impaired driving fatalities in the United States to date (NASEM, 2018; Teutsch and Naimi, 2018). The report (written by a prestigious committee assembled to review the impaired driving problem) provides a blueprint to solving the problem by identifying evidence-based and promising policies, programs, strategies, and system changes to

increase nation progress in reducing alcohol-impaired driving traffic fatalities. Among many other recommended strategies, those pertinent to this study include:

1. Local governments should adopt and/or strengthen laws and dedicate enforcement resources to stop illegal alcohol sales (i.e., sales to already intoxicated adults and sales to underage persons).
2. Local law enforcement agencies should conduct sobriety checkpoints in conjunction with widespread publicity to promote awareness of these enforcement initiatives.
3. Municipalities should support policies and programs that increase the availability, convenience, affordability, and safety of transportation alternatives for drinkers who might drive otherwise. This includes permitting transportation network company ride sharing, enhancing public transportation options (especially during night time and weekend hours) and boosting or incentivizing transportation alternatives in rural areas.
4. Every state should implement DWI courts and these courts should include available consultation or referral for evaluation by an addiction-trained clinician.
5. All states should enact all offender alcohol ignition interlock laws. To increase effectiveness, states should consider increased monitoring periods based upon the offender's BAC at the time of arrest and past recidivism.
6. States should enact per se laws for alcohol-impaired driving at .05 BAC and accompany enactment with media campaigns and robust and visible enforcement efforts.

Introduction

Mobility of people and goods is an essential need of modern societies. Land, air, and marine transportation are on the rise globally at present causing inevitable conflicts with wildlife. These interactions are the most pronounced in land transportation as road and railway infrastructures are widespread and will even be expanding in the coming years. Domestic animals are usually part of traffic and their owners have to obey the regulations. Wild animals, on the other hand, cross the road without warning for many reasons, and therefore cause serious traffic safety issues in numerous countries. Animal-vehicle crashes (AVCs) represent significant percentages of all officially registered crash records in a great number of countries and these, particularly with large mammals, are growing worldwide. The primary cause of this increase is the growing number of game species followed by rising traffic intensity as well as improved registration of these crashes.

Conflicts between transportation and animals are not only related to land transport, however, incidents between planes and flying birds or bats are very often reported. More than 13,000 bird strikes are reported annually in the United States. Despite the fact that even state-of-the-art aircraft can be endangered by such crashes, particularly when birds hit the aircraft front window or are sucked into the engines, the numbers of major accidents including human fatalities are very low. An example of this kind of crash was the collision of a passenger aircraft with a flock of birds in 2009 known as the “Miracle on the Hudson” when Airbus A320 landed safely on the river. Apart from these events, aircrafts sometimes collide with animals during take-off.

Collisions of sea mammals or large fishes with boats are often reported. The enormous size of many vessels prevents passengers from injuries. The situation is, however, different when whales collide with rapidly moving ferries or yachts. Whales even occasionally attack small yachts as a result of their erroneous determination of the floating object. Many yachts have been destroyed as a consequence of such encounters.

Collisions with animals are also frequently reported on railways. The extreme mass of railway vehicles protects passengers from injuries from AVCs. Relatively high portion of these crashes are therefore reported only when a considerably large animal is struck or when trains collide with herds of wild or domestic animals. Many videos from locomotive cabins exist on social media, which document animals’ behavior in front of an incoming train (Video 1). Deer typically use rail tracks in the winter when these are the only places without deep snow. Derailments are reported as a result of crashes with domestic animals at local railways, but also took place when a German high-speed train derailed after a crash with a herd of sheep in 2008. This article will focus on animal crashes, which take place on roads, as the road network is considerable denser than the railway network and often intersects natural habitats of wildlife.

Figure 1 Roe deer occur in high numbers in certain countries. They are habituated to traffic and thus can be seen quite often in herds resting not far from roads, Czechia. Source: Photography: Miloslav Kratochvíl.

Where Do Animal Crashes Occur?

Geographic Distribution of AVCs and the Species Involved

The road network spans the globe intersecting the habitats of native wildlife species. Crashes with wild animals thus logically occur, but in much higher numbers than people usually realize. The numbers of reported AVCs are rising over the last decades in numerous countries. Ungulates contributed the most to these statistics. The frequency of ungulate-vehicle collisions rose as a result of increase in their population, for example, white-tailed deer (*Odocoileus virginianus*) in the United States and roe deer (*Capreolus capreolus*) in many European countries (Fig. 1). The enormous growth of wild boar (*Sus scrofa*) population has been documented throughout Europe. They live in almost all of Europe today. Recently, wild boars were observed as far north as the central parts of Sweden and Finland.

Each continent and biogeographical region has its own representatives of large fauna, usually mammals, which are involved in motor vehicle crashes. Northern European countries, as well as Russia, Canada, and United States, report a number of crashes with deer, particularly moose (*Alces alces*) as the largest member of the *Cervidae* family (Sullivan, 2011; Sáenz-de-Santa-María and Tellería, 2015; Niemi et al., 2017). North Africa and Middle Eastern countries often report crashes with camels, while in Australia drivers collide frequently with kangaroos (Rowden et al., 2008). In South America, drivers meet Giant Anteaters, Capybaras, or domestic llamas on roads. Large fauna also occur on roads in South Africa (Fig. 2). Carnivores are generally less common than herbivores, but in certain countries crashes with carnivores are also often reported (e.g., Eastern European and Balkan countries report a number of crashes with wolves and bears).

Clustering of AVCs Along Roads

While the geographic distribution of roads and their density influence the overall number of AVCs, the local AVC pattern can also be investigated. It was found that AVCs occur in certain places along roads or railways with higher frequencies than in other parts. For example, 34% of all registered crashes with roe deer took place on less than 1% of the Czech road network. These places can be identified, using spatial statistic approaches applied to crash data, if AVCs were reported with a sufficient positional accuracy. Places where crashes concentrate, so-called hotspots, reveal specific local characteristics, which influence and explain the observed high concentration of crashes. These *local factors* need to be further studied, analyzed, and mitigated, where possible (Bartonička et al., 2018). Typical local factors are the view and the overall visibility for drivers, the existence of shrubs or trees

Figure 3 Relative frequency of reported AVCs involving roe deer in the Czech Republic. Lines represent the times of sunrise and sunset, respectively. Crashes with roe deer occur with the highest frequency shortly after sunset in May. Source: Data come from www.srazenazver.cz; Graphics by R. Andrášik (CDV).

close to roads, the existence of guardrails, etc. Proper identification of animal-crash hotspots is necessary for consequent effective targeting of mitigation measures. This fact is particularly important as a lot of mitigation measures are costly and their application should be focused first and foremost at the most hazardous places.

When Do AVCs Occur?

It has been determined that peaks of animal crashes occur around sunset and sunrise. This is influenced by periodic animal activity, which can be observed over years and days. Taking into account the fact that traffic intensities are usually low during sunset, the risk of AVC is therefore high. In addition, the crash frequency with animals is not stable over the year (Fig. 3). Two distinctive peaks can be found, for example, for ungulates, during the spring and autumn and another smaller one related to rutting of roe deer occurs between July and August (Steiner et al., 2014).

Consequences of Animal Crashes

More than one million deer-vehicle crashes occur every year in the United States resulting to approximately 200 fatalities (Huijser et al., 2007). According to CARE data, the European Union's road accidents database, more than 3000 human fatalities and serious injuries were recorded in Europe between 2011 and 2017. The situation is apparently the worst, in light of the absolute number of casualties, in Sweden due to the abundance of moose and in Germany and France because of their large road networks.

Despite the fact that less than 5% of wildlife-vehicle crashes result in human injury in general, geographic differences are enormous (Langbein et al., 2011). It depends on the weight and height of the animal involved in the crash (Jakobsson et al., 2015). The highest risk of fatal human consequences is with large mammals, for example, moose or camel. The moose is a large animal (Fig. 4). An adult moose weighs between 200 and 700 kg and its height in the shoulder ranges between 1.7 and 2.1 m (Fig. 5). It also has long legs. If a standard passenger car collides with a moose at high speed, the moose's large body rotates over the engine hood and lands on the windshield (Video 2). Such collisions are capable of causing substantial injury to the vehicle occupants

Figure 5 A comparison of relative heights of selected species which frequently collide with motor vehicles and the height of an average personal car. Source: Author: Vojtěch Nezval, CDV.

Figure 6 A comparison of car damage due to a crash with a wild boar (A) and a model of a moose (B). The smaller and lighter wild boar usually interacts with the bumper, while the larger moose interacts with the windscreen. This is often followed by a damage of car roof. Source: Photography by Generali (Czech Republic) and Jan Wenäll (VTI, Sweden), respectively.

(Fig. 6). The same mechanism can be expected with crashes with camel, horse, and red deer. Passenger car crashes are logically the most frequently reported, as these kinds of vehicles are the most abundant.

Animal crashes are, however, also reported with other types of vehicles including motorcycles and even bicycles. Motorcyclists in particular are extremely vulnerable road users as they usually drive at high speed and their stability and passive safety is significantly lower when compared to cars or trucks. Motorcyclists are therefore overrepresented among the group of injured and deceased drivers when related to crashes with animals.

In certain situations, avoiding crash with an animal is a more dangerous maneuver than a crash. This is particularly true when roads are not *forgiving*, that is, when trees are planted on road verges or other solid objects are placed there, for example, advertisement panels. Crashes into mature trees have very high fatality rates in the long run. Moreover, many fatal crashes to trees on local roads occur in night hours. It is therefore possible that some of them were a result of avoiding a collision with wildlife. Rational road verge management, focusing on forgiving roads, is necessary to avoid the negative consequences when cars travel off the paved road (Figs. 7 and 8).

Crashes With Domestic Animals

For the period of 2010–18, on average, between 300 and 500 crashes with domestic animals were registered on Czech roads annually. It is very less as compared to more than 70,000 crashes reported with wild animals over the same period (7,800 annually on average). Certain domestic animals have a different daily activity pattern than wildlife. Crashes with them therefore take place in different parts of the day than those with wildlife. Moreover, domestic animals are often utilized as engines, particularly in the developing world. Such animals, when frightened, might cause a collision with traffic. It is therefore advised to drive carefully when

Figure 7 A sketch demonstrating that a hazardous situation can result in fatal outcomes when an animal enters the road. Whereas a crash with an animal, up to the size of a roe deer, usually means car damage (1), drivers are sometimes trying to avoid collisions, which can result in a frontal crash to an incoming vehicle (2) or to a tree (3). These situations can only occur on secondary roads without central and side guardrails or where there are no wide road verges free of trees. Source: Author: Vojtěch Nezval, CDV.

Figure 8 An example of a secondary collision due to AVC: a van hit a tapir (see the carcass of the tapir in the middle of the figure), then the driver lost control of the vehicle which consequently crashed into a large lorry. The lorry exploded and nine people died on September 2015, BR-267 Highway, Mato Grosso do Sul State, Brazil. Source: Photography: LTCI-IPE-Brazil.

passing an animal-powered vehicle. The highway law in Maine (USA) mentions these situations in point 3 (Frightened animals) as follows: When a person riding, driving, or leading an animal that appears to be frightened signals by putting up a hand or by other visible sign, an operator approaching from the opposite direction must stop as soon as possible and remain stationary as long as necessary and reasonable to allow the animal to pass. Situations when large herds, for example, sheep, cows, are grazing close to a road, where there are no fences, represent a danger to traffic. Crashes with dogs, which often move freely close to human settlements, are also quite frequent.

Cost of Animal Crashes and Impact of Roadkill to Wildlife

Overall economic losses from AVCs are enormous due to the extremely high number of these events. The majority of losses are related to car damage. Whereas domestic animals usually have an owner who can be responsible for a crash, this is not generally true for wild animals. Game species in certain countries belong to a hunting association, but costs related to crashes can only be covered

by car insurance. Vehicle-related damage, but also the loss of a domestic animal, which is being used for livelihood in developing countries, and related emotional losses are often part of the AVC outcomes.

While animal crashes mostly represent only an issue related to vehicle damages, a number of wild animals die or suffer from injuries. It was also determined that certain species can even be endangered by extinction due to roadkill, particularly for species with low population sizes and low growth rates. This threat is not, however, only directly related to roadkill. When adult animals, which are feeding youngsters, die due to roadkill, it can also affect the youngsters who consequently die as a result of starvation. The fact that the overall number of roadkill and the species involved were not known recently led to the development of wildlife-crash reporting systems in many countries.

Animal-Motor Vehicle Crash Databases

Transport agencies, motorway, and transport police record data on traffic crashes on a daily basis. National crash databases are therefore useful sources of information about this phenomenon. A well-known fact about animal crashes is their underreporting. One of the reasons is that the crash data are only gathered when the minimal damage cost is exceeded or a human injury took place. It has been estimated that the total number of collisions involving motor vehicles and large animals has been underestimated by 20%–30%, although some local officials and hunters go as far as evaluating this underestimation by as much as 50%. The situation related to small animals is, logically, even worse.

Systematic, precise, and consistent data, particularly related to species involved in AVC, are therefore needed. Many ad-hoc AVCs reporting applications, usually utilizing a citizen science approach, have recently been developed to overcome these issues. Some of them have been statewide, but the majority only regional coverage. Readers could be interested in seeing some of the websites: California roadkill observation system in the United States (<https://www.wildlifecrossing.net/california/>), Project Roadkill in Austria (<https://roadkill.at>), Srazenazver.cz (Fig. 9) in the Czech Republic (<http://www.srazenazver.cz/en/>), Taiwan Roadkill Observation network (<https://roadkill.tw/en>), Project Splatter in the United Kingdom (<https://projectsplatter.co.uk/>), and Animals under wheels in Belgium (<https://waarnemingen.be/vs/start>). These databases can be useful sources of information where AVCs occur and which species were involved. Data can then be analyzed in order to identify places where the crashes concentrate as well as other important factors including species distribution, crash circumstances and consequences, date of the crashes, etc.

Figure 9 An example of AVC reporting system. Srazenazver.cz combines data from traffic crashes reported by Police data from volunteers and road administrators. Hotspots are identified online and graphs and maps are generated.

How to Avoid Crashes With Animals?

How do animals behave when close to roads? Researchers determined that several kinds of animal behavior related to road crossings exist. Small animals usually do not see roads and the traffic there is dangerous and are therefore consequently killed in high numbers (e.g., a great number of species of amphibians and reptiles). Other species, in contrast, react to incoming traffic with defensive behavior (e.g., hedgehogs) and are then killed as well. Other groups of species try to escape. This behavior is typical for roe deer, which are the most frequently involved in the recorded crashes in Europe. Its behavior can be seen, from the drivers' perspective, as chaotic and nonlogical. Many drivers, who collided with deer, reported later that the deer was running alongside their car and then, suddenly, jumped in front of the car.

Deer often use trees and shrubs in road verges as shelter or a source of food particularly in highly intensive agriculture landscapes where there is a lack of these sources. The availability of forage, water bodies, feeding, and resting places close to roads are likely to increase the presence of animals. There is therefore an eminent danger to traffic when animals decide to cross roads or are alarmed and escape consequently by crossing the road. High traffic volume roads may also deter certain animal species from crossing. Roads can act in these cases as a barrier to free animal movement. Many recommendations currently exist as to how to lower the number of AVCs. They can be divided into two main groups: information for drivers and approaches influencing animal behavior.

Information for Drivers

Drivers are often surprised when an animal comes closer to a road or is crossing immediately in front of a car, as has been reported many times by patients who have sustained AVCs. All drivers have to be therefore cautious when spotting animals close to roads or when going through forested areas.

Drivers should take note of road traffic signs. It has been shown earlier, however, that static warning signs can be ineffective. Driver simulator studies have demonstrated that drivers respond with a greater velocity reduction to AVCs countermeasures, which are considered novel, such as a radio-warning message (Jägerbrand and Antonson, 2016). New driver-warning systems are therefore currently being developed. Usually infrared-based systems are installed along roads in places where frequent movement of animals is expected. They are activated, that is, flashing and informing drivers about a potential danger, when animals are detected close to a road. It was also found that drivers who frequently use a road could even be habituated to these active signs, particularly when they produce a significant portion of false positive information. These systems should only be active when animals are detected close to a road. It has been shown in the United States that these temporary warning signs were well-lit at night during deer migration periods and reduced the number of deer road-kills at experimental sites compared to control sites.

Speed reduction is recommended as safety behavior for drivers, which reduces energy significantly during a crash with an animal. Speed reduction zones are therefore recommended in crash-prone areas, but they should also be dependent at the time of day. Deer often move in groups. Drivers should be ready for the other animals, particularly when one of them has just crossed the road before their cars. Breaking and then colliding with an animal is also recommended when an animal steps suddenly in front of a car. There are only a few exceptions, related to large mammals, when the crash could have worse outcomes for passengers than avoidance maneuvers. In these cases, practitioners suggest aiming at the back of the large animal, for example, a moose.

Measures Targeted to Animals and Their Behavior

Plenty of measures have been developed to influence animals and avoid animal crashes. No universal measure exists; however, as the animals differ significantly in their behavior, body sizes, and life cycles. Roads and other transportation infrastructure should be planned and designed in such a way so as to keep in mind this phenomenon of animal crashes. Animals cross the road for many reasons. Regular seasonal migration of large herds of ungulates poses a traffic safety issue in North America. Migration of pronghorn (*Antilocapra americana*) across the western United States has been studied thoroughly and many crossing structures have been built recently in order to avoid crashes with motor vehicular traffic. Such large continental migration is not typical in densely populated Central Europe. Game species (wild boar, roe deer) live within rather small areas there. The majority of crashes are caused there due to their daily movement. Daily movement of animals, which have relatively small areas, can be sufficiently affected by installing feeding places or ponds at the same side of roads where they live. Territorial behavior of animals (e.g., roe deer) occurs in only certain parts of the year and can therefore be predicted.

Animals are attracted to roads for certain reasons. Salt is often used during the winter in northern countries to help with the road maintenance. Ungulates are attracted, however, to roads and lick the salt blocks. This behavior is risky as the animals often cross the road when finding other sources of salt. Winter road maintenance should therefore use different substances than salt to de-ice road surfaces. Some animal species, for example, moose, use transport corridors for travel during periods of deep snow (Video 1) as well as for feeding.

Fruit trees or other vegetation provide both forage and shelter for animals and thus increase the attractiveness of such habitats along roads. Another source of food along roads comes from food remains, which drivers and passengers throw out of the cars in rural areas thus attracting animals close to roads. Scavengers are also attracted to roads when carcasses are left on or close to roads for a longer time. Asphalt road pavements accommodate energy over hot days and are therefore warmer than the natural neighborhood in the nighttime. Certain species lie on the surface during nights, utilizing this warm surface, and can be killed by incoming vehicles or cause a crash when drivers are avoiding collisions. These cases may result in a higher concentration of animals around the roads and the risk of crashes.

Certain wildlife species, particularly game species, are overpopulated. This is the case in many Central European countries. A number of authors have recommended targeted herd management, that is, the reduction of the animal population size through hunting to decrease the number of animals and then indirectly the number of animal crashes. In certain parts of North America, large boulders along roads are also considered as an effective preventive measure to block deer from entering roads. It has been observed that ungulates, in particular, hesitate to go over large boulders. Systems consisting of iron bars (cattle grids), allowing cars to go from roads to the adjacent service forest roads, were also already installed in Europe. These measures are effective barriers to deer, but not for wild boar as was observed.

Vegetation removal at road verges is also a recommended measure (Rea, 2003). It makes road verges safer for drivers and increases driver visibility. However, young vegetation, when road verge management is not done carefully, can attract ungulates close to roads. This is particularly true for moose, which prefer vegetation growing in open areas adjacent to forests. Animals, when resting in shelters, as is common in open or intensively used agricultural areas, can be alarmed by, for example, a free ranging dog, tourists, an agriculture vehicle, etc., and then escape by crossing a road thus causing danger to road traffic.

The most effective structures preventing AVCs are fences (Huijser et al., 2007). They can, however, create an almost absolute barrier to animal movement. Fencing should therefore be used in association with wildlife crossing structures (also called fauna passages) such as over- and underpasses (Fig. 10). Fencing ranks among the most expensive measures. Maintenance costs are considerably high when this measure is applied to a large part of the road network. It has been shown that broken fences, or fences, which are interrupted, can have an even worse effect on traffic safety than roads without them. The reason is that animals can enter the area around a road, but then they are not able to find their way out and are caught in a closed corridor (Fig. 11). Fences have to be checked regularly for consistency and overall conditions, as many animals are able to dig under or even destroy them (e.g., wild boar). Connections between fences and other structures, such as overpasses or bridges, also pose a weak part of these systems. However, poor connections with space, of about half of 1 m wide, can often be seen. This is still enough space to allow certain ungulates to go through and enter the area around roads.

Figure 10 Overpasses, when accompanied with fencing, are highly effective measures against animal-vehicle crashes. A so called green bridge “Ivaceno brdo” on “A1” highway (E71) between Zagreb and Split (Croatia). Source: Photography: Djuro Huber.

Figure 12 Reflectors mounted on bollards are being used particularly in Central European countries to deter animals from crossing roads. An example from Styria (Austria). Source: Photography: Wolfgang Steiner.

Measures Suitable for Secondary Roads

In most of the countries, motorways are usually fenced nowadays and therefore safe in the view of crashes with large mammals. Rural roads and roads in certain developing countries are, on the other hand, regularly crossed by animals, thus causing potentially dangerous situations for drivers and car passengers. There is almost no controversy that the motorways should be equipped with fences accompanied with fauna passages, rural, and low traffic volume roads need less expensive but still effective solutions. Which measures can be used to follow the above-mentioned criteria of financial effectiveness? Current research has not still offered the explicit answer. Many measures were suggested, developed, studied, and tested.

For example, *olfactory repellents* are installed at high numbers across the central European countries. The odor usually consists of foam injected with scent, which mimic predators' or humans' scent. It is believed that animals, particularly ungulates, should be more cautious when crossing roads fringed with these repellents. Results from few dataset currently available are, however, not unequivocal. More research is still needed. The same is true for assessment of the effectiveness of *wildlife warning reflectors* (Fig. 12), which were in high numbers installed across the German roads recently, but only brought ambiguous results. The reflectors are supposed to deter particularly ungulates from entering the road by reflecting the lights of incoming vehicles aside, to the road verge. Some authors argue that even if these devices were not capable to deter animals off roads, and to directly decrease the number of crashes, they could serve at least as a warning for drivers. Drivers, when notice the presence of a mitigation measure of such a kind, they could slow down. *Wildlife whistles* mounted to vehicles were tested in the North America, but also here the results were rather negative. Moreover, concerns remain, if such high ultrasound will not alarm the animals and will cause their panic behavior including crossing roads.

Problem of habituation to some measures is typical for those, which should only warn animals when entering roads. Many studies focused only on data from relatively short periods. Moreover, it is not still clear how the animals behave and react on many of warning devices, as there almost were no behavioral studies conducted. Animals are, however, intelligent creatures and are to a certain extent able to understand that some measures pose no actual danger to them.

Monitoring of Animal Behavior

Knowledge of animal behavior and their daily and seasonal movement is important for predicting when and where crashes occur. Recent technological progress allowed for the development of both light and endures motion detectors, which can be, in a form of a GPS collar, attached to animals. This helps researchers understand certain basic principles of animal movement. Mitigation measures, once installed, have to be monitored regularly and repaired when necessary. Only fully functional measures are able to deter animals from crossing roads. The effectiveness of mitigation measures has to be evaluated regularly and cost-benefit analyses should always be performed to ensure that the counter measures would also be cost-effective.

Animal Crash Awareness Among Public and Educational Programs for Drivers

The probability of animal crashes can be lowered to a certain extent. Drivers should be aware that the majority of crashes with wildlife occur during twilight and night. Poor driver visibility in night hours or due to obstacles close to roads, for example, trees and shrubs, means that they will have less time to react if an animal appears in front of their cars. Therefore, drivers should travel at a lower speed when moving through forested areas particularly during the night. A lower speed also means lower energy released during a crash and this is particularly important as the kinetic energy is proportional to the speed raised to the second power.

Drivers can also learn on their own from watching instructive videos captured by dash cams mounted in many vehicles which their owners posted on the Internet and social media (e.g., YouTube). Certain common characteristics of crashes with animals can be identified from these records (Rea et al., 2018). Driving school curricula should contain information about these kinds of crashes

and the circumstances and such videos could also be a particularly useful tool. Swerving to avoid animals is often dangerous as it can result in run-off road crashes or a collision with other road users with severe consequences for car passengers.

The Outlook for the Future

Automobiles can be equipped with infrared cameras and thus inform the drivers about thermal-energy emitting objects, which cannot be detected within the visible spectra, occurring near roads during night hours or when there is a fog. Similar to the high-tech electronic systems, it is expected that the cost of these onboard warning systems will decrease once they become more commonplace on vehicles. The autonomous vehicles will also be equipped with technology which can identify animals moving along or crossing roads including animal detection systems or night vision assistants.

Introduction

One of the most important aspects to consider in the design of any mode of transport, such as passenger cars, railways, or aircraft structures, is crash safety or crashworthiness. Crashworthiness is defined as the capability of a structure to provide adequate protection to its passengers from injuries in case of a collision. The safety requirements are outlined by agencies and organizers of a specific travel mode or competition; to meet these regulations, designers must manufacture energy absorbing systems, called impact attenuators. These can be fitted in front of bridge abutments and other unforgiving structures as well as designed into the vehicle in front of the survival area occupied by the driver and passengers. Impact attenuators are generally made up of aluminum, honeycomb, fiber-reinforced polymer (FRP) composites, or a combination of these materials that provides maximum protection. The deformation of such components should absorb the highest level of kinetic energy while transmitting low load uniformly to the rest of the vehicle and to the vulnerable components (e.g., driver and passengers) maintaining an acceptable level of crushing. The use of lightweight materials may contribute also to improve the acceleration performance and fuel economy of the vehicle.

Many research teams have investigated the behavior of empty or foam-filled aluminum tubes or honeycomb structures under axial quasi-static and dynamic loading conditions using both experimental and numerical techniques (Boria, 2010; Chirwa et al., 2003; Hanssen et al., 2000; Hsu and Jones, 2004; Langseth et al., 1999; Munusamy and Barton, 2010; Rappolt, 2015). According to the literature, honeycomb structures are relatively light in weight and absorb more energy than other combinations (i.e., empty or foam filled). However, a large block of honeycomb occupying the whole volume of the impact attenuator is a heavy and expensive option and it may be advantageous to combine the benefits of thin-walled structures and honeycombs in a single system.

More recently, the attention has shifted toward FRP materials because of their advantages of lightweight, high strength, corrosion resistance, and easy manufacturing (Davies, 2000; Fuchs et al., 2008; Smith, 1990) compared to conventional materials (Jacob et al., 2002). Consequently, the use of composite crushing absorbers is increasing and today it is more common to find them applied in many high-performance vehicle structures like in sports cars, high-speed trains, and helicopters. Initially, in order to reduce the vehicle weight, glass fiber reinforced plastic composites were adopted. Their replacement to conventional materials into specific vehicle allowed a weight reduction from 40% to 60% and better performance (Ning et al., 2007a, 2007b, 2009; Thattai parthasarthy et al., 2006). More recently, carbon fiber reinforced plastic (CFRP) composites are replacing metallic components for crashworthiness applications, as attested by extensive numerical and experimental research (Boria, 2013; Feraboli and Masini, 2004; Ghasemnejad et al., 2010; Hwang et al., 2011; Mamalis et al., 2005; Yang et al., 2007).

The main advantage of composites respect to conventional materials under crush may be attributed to the different type of crushing behavior. Contrary to conventional structures, in fact, FRP composites fail through a combination of several different fracture mechanisms (Guimard et al., 2009; Guoxing and Tongxi, 2003; Jumahat et al., 2010). These complex failure modes, that involve interlaminar failure, fiber-matrix debonding, fiber pull-out, matrix deformation/cracking, and fiber breakage, together with friction effects, contribute to the overall energy absorption and give composite structures a greater specific energy absorption (SEA) than metallic ones (Mamalis, 2005a, 2005b; Mamalis et al., 1997A). If subjected to axial loadings, such structures commonly take

the form of thin-walled tubes of circular and rectangular cross section produced with fabric prepreg obtained from the combination of fibers and resin of different nature. The structural response depends also on the technology adopted for their production. The ability to predict their behavior tends to be complicated due to the heterogeneity of structural properties and manufacturing variability. This number of effects makes the design of composite energy absorbing structures much more complex than when using metals, which are extensively used for this kind of applications.

In crashworthiness design, finite element (FE) simulations play a very important role thanks to their possibility to predict behavior in early design phases, so enabling cost reduction and shortening of the design phase. The energy dissipation by plastic deformation in ductile metallic structures is well understood and may be modeled by elastic-plastic material models in FE analysis, reproducing good levels of predictability. The modeling of composite crushing phenomena, on the other hand, is still developing given the complexity and heterogeneity of the material. There are various approaches in modeling composite structures: micro-mechanical and macromechanical ones. In the first approach, there is a high consumption of computational resources and, therefore, it cannot be applied for complex structures. It is therefore important to develop models that are simple enough to be employed in practical analysis situations, but at the same time capable to provide results with a suitable level of accuracy.

The aim of this article is to focus on the methodology to follow in order to design a specific impact attenuator made of conventional or composite materials under dynamic loading. Conventional materials are typically applied as sandwich structures, with external layers in aluminum and internal aluminum honeycomb core, with a truncated pyramidal shape, and such structures were subjected to axial dynamic loading as analyzed by [Boria \(2016a\)](#). In case of composite material, the design was focused on a CFRP structure. A prepreg obtained from high-strength carbon fibers, arranged in a canvas in a balanced manner and immersed in an epoxy resin was adopted. The frontal impact attenuator of a Formula SAE car was investigated ([Boria, 2016b](#)), whose geometry is like a truncated pyramidal structure with rounded edges to get closer to taper. Previous research has demonstrated, in fact, that cones are more suitable for impact structures than tubes since they do not require crush initiators ([Meredith et al., 2012](#)); furthermore, they more accurately reflect real-life geometry found in the automotive and motorsport arenas than simpler plate type specimens. The experimental tests should be correlated with a numerical analysis; therefore, specific FE models to simulate the collapse mode of such structures and predict their energy-absorption capability were developed using the nonlinear explicit commercial code LS-DYNA. For each analysis, the numerical results were compared with those obtained from real axial crushing tests. The overall aim is to investigate whether such structures (in conventional or composite material) can be used for designing an impact attenuator for a specific application. After the comparison between numerical and experimental data, it was observed how the proposed configurations can absorb impact energy with deceleration values coherent with the specific homologation references.

Vehicle Passive Safety

In general, it is possible to divide the vehicle safety into two disciplines: active and passive safety ([Lukaszewicz, 2014](#)). Preventing the occurrence and likelihood of a crash is under the active safety activities, while passive safety aims to reduce or mitigate the severity of a crash for the vehicle structure, the occupants, and other involved crash partners. During a crash incidence the body in white of a vehicle must protect the passengers and reduce the crash severity by allowing controlled energy dissipation through structure deformation. When evaluating real-world crashes involving at least one car, the most widespread crash events are frontal impacts, followed by side and rear ones.

In the last couple of decades, passive safety requirements have continuously increased and today vehicles need to pass a certain set of legally defined tests in order to be allowed to be sold. In addition, the implementation of new car assessment programs (e.g., NCAPs, IIHS) has started; such programs want to define tests that emulate real-world crash cases in order to allow a comparison between different vehicles.

Initially, impact attenuators were designed in conventional material, using steel or aluminum structures. The crashworthiness benefits of composite materials were first recorded for applications in helicopters and Formula 1 vehicles. In 1980 McLaren introduced a chassis as a safety cell made from aluminum sandwich with carbon-epoxy face sheets. In 1985 frontal crash tests were introduced and most Formula 1 teams adopted a composite monocoque and a nose cone to follow these new regulations. Since then, side impact tests (in 1995), rear impact tests (in 1997), and lastly side intrusion tests (in 2001) have been introduced. As a result of this, the fatality rate has decreased over time.

The crashworthiness design is based on the research of the best geometric and material configuration of the attenuators, in order to get a vehicle deceleration history during impact that has the desired characteristic of progression ([Belingardi and Chiandussi, 2011](#)). In a passenger car the structures designed to absorb energy are in the front ([Fig. 1](#)), placed between the front bumper and the passenger compartment. The front structure generally consists of four longitudinal thin-walled beams, two for each side of the vehicle; two are positioned in the upper part of the engine compartment, just below the hood, and two, generally of bigger dimensions, at an intermediate height behind the bumper. In recent vehicles, at the front extremity of these two main beams, two so called defo-box or crash boxes are placed, one at each side. These crash boxes are intended to absorb energy in case of impact at low velocity, so avoiding large structural damage to the other parts of the front structure. Just behind the front bumper there is a transverse beam, also called front end module, aiming to position and support the bumper; it is connected at its extremities to the longitudinal main beams through the defo-boxes.

Overall, the front section of a vehicle, in terms of crash performance, is governed by requirements for stiffness, energy dissipation, and controlled deformation to enable good occupant protection. All three goals can be simultaneously achieved using lightweight

Figure 1 Front bumper assembly of a recent vehicle: (A) real, (B) model.

materials, such as aluminum, sandwich structures, or composite ones. However, it is the energy dissipation of composites that has widely been researched due to the potential improvements in performance and weight.

Energy Absorbing Deformation Mechanisms

The behavior of attenuators under axial loading conditions heavily depends on the material used. In metallic materials, energy is dissipated through plastic folding, work hardening and adiabatic losses during heating. Composites, by contrast, dissipate energy through external and internal friction, bending of the fibers and kinematic dissipation through fragmentation (**Fig. 2**).

Composite materials may offer many potential benefits for improving crashworthiness. Primarily, the SEA may be significantly higher, that is, composites may achieve the same level of crashworthiness as current metallic structures at a fraction of the weight. Lastly, composites deform by brittle fracture, unlike metals that deform by plastic crushing. During brittle fracture the whole component can be disintegrated, while for structures exhibiting plastic folding, the hinges limit the foldable length. This may have potential benefits for optimizing the deceleration of the vehicle, which can occur over a longer distance and thus resulting in a lower overall deceleration, which reduces the risk of secondary impacts (**Barnes et al., 2011**).

According to **Hull (1991)**, the principal deformation modes of energy absorbing for composite structures can be classified into the following categories:

- global buckling,
- progressive folding, and
- progressive crushing.
 - progressive splaying and
 - progressive fragmentation.

Generally, the first deformation mode absorbs very little energy; therefore it is undesirable for energy absorption applications and must be prevented for both conventional and composite materials.

Progressive folding is the typical deformation mode of metallic structures but may also be found in ductile FRPs and metal/FRP hybrid materials. It is characterized by a sequence of localized folding at the crush front, propagating away from the impact point through the structure. The SEA of a structure able to collapse into such mechanism can reach intermediate values, even if it cannot reach

Figure 2 Comparison between plastic folding in metals (A) and brittle fracture in FRP composites (B).

Figure 3 Sequence of deformation events during progressive crushing (Johnson and David, 2010): beginning of the crushing process (A), beginning of frond bending (B), and fully established crush front (C).

Figure 4 Schematic representation of formation of a fragmentation-mode crush zone (Hull, 1991).

the same levels as progressive crushing due to a lack of mechanisms for energy dissipation. The fact that this type of deformation was observed for some aramid and glass fiber reinforced specimens, as well as for some thermoplastic fiber reinforced composites, leads to the conclusion that a high strain to failure for the fiber and matrix is necessary for this deformation mode to occur.

Progressive crushing is the deformation mode typical of composite structures that are able to exhibit the highest SEA value. It can be divided into two main modes, progressive splaying with the formation of internal and external fronds (Fig. 3) and progressive fragmentation where a stable crush zone is established progressing down the structure, away from the point of initial contact (Fig. 4). In general, both progressive deformation modes may occur in any structure and the exact sequence of events resulting in either splaying or fragmentation it may strictly depend on the specific configuration of the specimen (e.g., fiber and matrix material, stacking sequence, manufacturing technology, geometry, trigger mechanisms) and on the test conditions (e.g., test speed, test direction, temperature).

According to Mamalis et al. (1998), the failure modes at macroscopic scale for a composite structure can be summarized into four major modes, depending on structural dimensions, material properties and testing conditions (Fig. 5). It is possible refers to them with the terminology Mode-I, Mode-II, Mode-III, and Mode-IV. Together with Mode-I and Mode-IV that correspond, respectively, to progressive crushing and progressive folding, already indicated by Hull, there are two other failure modes that can occur if the attenuator is not well designed. When the attenuator presents some edges, such as a square frustum, the undesirable failure Mode-II could occur, where it is evident a longitudinal crack progression along the edges of the structure. Moreover, it is possible to observe a centrally confined circumference crack (Mode-III) that, together with Mode-II, guarantees a low energy absorption capability and implies a catastrophic failure to avoid. Therefore it is evident that an impact attenuator should be designed to produce a Mode-I or a Mode-IV crushing mechanism, regarding mainly composite and metallic material respectively, as the structure guarantees the highest energy absorption.

Contrary to conventional materials, thin-walled composite structures under axial compression do not present a sequence of plastic hinges that in terms of force-displacement trend corresponds to low and high peaks (Fig. 6A) but are characterized by an almost constant crushing strength throughout the entire crushing process (Fig. 6B). The value of the peak load and the drop from it to the average crushing load are strongly dependent on the trigger geometry (Garner and Adams, 2008). As closer to the mean force value is the diagram, without high fluctuations, better is the designed attenuator because very similar to an ideal absorber.

Figure 5 Collapse modes: (A) mode-I, (B) mode-II, (C) mode-III, and (D) mode-IV (Boria and Pettinari, 2014).

Design of an Impact Attenuator Made of Conventional Material

Impact Attenuator Definition

As mentioned before, the impact attenuator is such safety structure installed on a car that could absorb energy during frontal collision by progressive deformation. Such structures should be lightweight, resistant and deformable enough to limit the force and deceleration transmitted to the driver; moreover, it is necessary to design it according to specific technical regulations. For the FSAE rules (SAE, 2016), the impact attenuator must be installed in front of the bulkhead and must have a length, height and width of 200 mm, 100 mm and 200 mm, respectively. During the impact, it should not penetrate the front bulkhead and the total deformation must be limited to the attenuator. In the impact event of the vehicle (300 kg heavy) against a solid and nonyielding barrier at the velocity of 7 m/s, the attenuator must give an average deceleration of less than 20 g, a peak lower than 40 g and the total energy absorbed must be at least 7350 J.

In literature it is possible to find several studies on the design of impact attenuators in conventional material (Belingardi and Obradovic, 2010; Imanullah et al., 2018; Li et al., 2017; Munusamy and Barton, 2010; Santosa and Wierzbicki, 1998; Zarei and Kroger, 2006).

The impact attenuator analyzed in such section was made of aluminum sandwich material with a honeycomb core separating two aluminum thin skins. The shape chosen for the crash-box is a truncated pyramid (Fig. 7). The five sandwich panels are joined together with aluminum L-shaped profiles riveted and bonded on the skins with epoxy adhesive.

Figure 7 Impact attenuator: (A) external and (B) internal view.

Figure 8 Schematic testing procedure.

Testing Procedures

According to the FSAE rules and in order to evaluate the crushing capability of the designed impact attenuator, dynamic experimental tests were planned and performed (Fig. 8). A mass of 300 kg is dropped from a height of 2.5 m, thus getting an impact velocity of 7 m/s, as requested by regulation. A piston driven by pressurized air operates the drop of the mass, able to fall in a controlled manner thanks to two steel ropes. The accelerometers, used to measure the mass deceleration, were placed on top of the mass. The impact attenuator was constrained by screws to a base of steel and concrete in order to reproduce the connection with the frame. A high-speed camera was used in order to capture the physical phenomenon, not visible to the naked eye; a sampling of 500 frames per second was implemented.

Numerical Simulations

In order to reproduce the crushing phenomenon numerically, a FE model was implemented. In particular, the explicit dynamic solver LS-DYNA was used employing the material properties obtained from dedicated experimental tests, such as out-of-plane compression test, three point bending test, buckling under in-plane compression and in-plane shear test. Due to the geometrical symmetry and in order to contain the computational time, only half attenuator was modeled (Fig. 9).

*MAT_PIECEWISE_LINEAR_PLASTICITY was used for the aluminum skins. The final failure of the external skins during the impact loading is characterized by a failure criterion. Failure means a loss of stiffness and it is detected when elongation of elements in any direction reaches the allowable strain. Among the different approaches available in modeling honeycomb structure, the core was simplified as an orthotropic continuum based on its effective material properties with solid elements (*MAT_HONEYCOMB). The car body and the barrier were idealized as rigid structures (*MAT_RIGID) assuming therefore that only the impact attenuator is responsible of the total kinetic energy absorption.

The total system, consisting of the impact attenuator and the car body idealized as a 300 kg mass attached to it, impacts the barrier wall at the velocity of 7 m/s, as imposed by technical regulation. Such contact was modeled using a node to surface contact, while in

Figure 9 Numerical model of the impact attenuator: (A) external and (B) internal view.

order to prevent elements penetration of the impact attenuator during crushing a single surface contact was added. The elements representing the core were directly connected to the skin nodes at the interface using a tied break contact.

The explicit dynamic simulation using LS-DYNA can start only after fixing some control parameters, such as termination time, time-step and output requests.

Results and Discussion

Fig. 10 shows the impact attenuator crushing during the real test every hundredth of a second. From the frames it is evident that the energy absorption was guaranteed from the progressive folding mechanism; plastic hinges tended to form in succession from the top to the bottom of the structure.

The final crushing of the attenuator after the test is shown in **Fig. 11**. From the picture it is also evident the integrity of the structure not subjected to the energy absorption; only the top of the attenuator was subjected to the plastic absorption.

Together with the experimental evidence, the analysis of the attenuator under axial loading should be juxtaposed with the acceleration signal. **Fig. 12** shows the acceleration raw data versus time acquired by the accelerometer during the experimental test. Since the deceleration peak of the raw data is greater than 40 g, it was filtered with the Channel Filter Class (CFC) 60 (100 Hz), as required by the FSAE Rules. Also, the filtered data are shown in **Fig. 12**: the deceleration peak of the filtered data is about 31.1 g and the average deceleration is about 14.2 g.

The aim of the designer is to reproduce also numerically the crushing phenomenon. **Fig. 13** shows the numerical final deformation of the impact attenuator. It is evident the plastic folding at the top of the structure and a more intact configuration on the bottom of the same, as in real test.

The acceleration signal versus time can be recorded during simulation thanks to output controls. **Fig. 12** reproduces also the variation of numerical accelerations in time, and it can be observed how such trend is very close to the experimental case, except for small differences. It is due to the simplifications adopted in the numerical model compared to the real structure.

Figure 10 Frames of the impact every 10 ms (impact starts at time 0.92 s).

Figure 11 Impact attenuator after test: (A) external and (B) internal view.

Figure 12 Acceleration-time: experimental results (raw data, filtered data, average value) and FEM.

Figure 13 Final deformation of the impact attenuator from the numerical point of view.

The following table summarizes the main results of the experimental and numerical tests for such an impact attenuator with a truncated pyramidal structure (**Table 1**).

It can be concluded that the designed impact attenuator is able to satisfy the specific homologation requirements of the FSAE, therefore can be used in front of racing car bulkhead during competition.

Design of an Impact Attenuator Made of Composite Material

Impact Attenuator Definition

In literature it is possible to find several studies ([Bisagni et al., 2005](#); [Heimbs et al., 2009](#); [Obradovic et al., 2012](#); [Wang et al., 2016](#)) on the design of impact attenuators in composite material, even if such research is still less respect to conventional materials and refers mainly to simple structures.

Table 1 Results of the experimental and numerical tests.

	<i>Test</i>	<i>FEM</i>
Time at the beginning of impact	0.922 s	0 s
Time at the end of the impact	0.972 s	0.048 s
Average deceleration	14.2 g	15.9 g
Peak deceleration	31.1 g	28.6 g
Final length of the attenuator	0.109 m	0.114 m

**Figure 14** Geometry of the impact attenuator.

The objective of this section is to present the results of a numerical and experimental campaign conducted on a CFRP structure in order to pass homologation test for FSAE requirement (SAE, 2016). The structure was manufactured using a carbon-epoxy preimpregnated fabric material (Obradovic et al., 2012). As regards the geometry a truncated pyramidal structure with rounded edges and various wall inclinations was chosen (Fig. 14).

Along the height of the structure three different zones were created varying only the wall thickness; such choice was dictated by the necessity to ensure a stable collapse, reduce the peak load and lighten the structure. The manufacture was obtained by hand lay up of preimpregnated composite layers and autoclave curing at 135°C and 7 bar applied pressure. Care was put on lamination process; it was avoided the overlap of the laminae at corner edges to guarantee the progressive crushing avoiding catastrophic failure under axial loading.

Experimental Dynamic Tests

The crushing behavior of the front impact attenuator was analyzed dynamically. The instrumentation consisted of a drop weight machine (Fig. 15A). Impact accelerations and velocities were acquired by a FA3403 tri-axial accelerometer with $\pm 500g$ full scale and a E3S-GS3E4 photocell, respectively (Fig. 15B and C). Moreover, a Mikrotron high-speed camera with a sampling of 1000 frames/s was used (Fig. 15D). In order to respect the FSAE regulation, the mass was fixed to 300 kg and the impact velocity to 7 m/s.

Finite Element Modeling

During the crashworthiness design is necessary to join the experimental campaign with the numerical modeling. Therefore specific FE models were done in order to reproduce, as faithfully as possible, the crushing behavior for the CFRP impact attenuator. The geometry was modeled following both the micro- and macromechanical approach. It means the implementation of solid elements plies with cohesive interface for the first methodology (Boria et al., 2015) and single shell layer model for the other one (Fig. 16).

The composite constitutive models implemented in LS-DYNA code are continuum mechanics ones. Composites are, therefore, modeled as orthotropic linear elastic materials within a failure surface. The exact shape of the failure surface is strictly dependent on the failure criterion used in the model. Beyond the failure surface, the appropriate elastic properties are degraded according to the assigned degradation laws, that can be divided into two main categories: progressive failure (for the material cards MAT 22, 54/55, 59) or continuum damage (MAT 58, 161, 162). In literature, it was shown how the progressive failure models can reproduce faithfully the brittle fracture of the composites under axial loading (Bisagni et al., 2005; Feraboli, 2008); it is therefore decided, for this study, to use the linear-elastic model *MAT_ENHANCED_COMPOSITE_DAMAGE. This material uses the Chang–Chang failure criterion (Chang and Chang, 1987) to determine individual ply failure. The deletion of the element occurs when all the layers fail.

Figure 15 Drop tower and instrumentation.

Figure 16 Different mechanical approaches used for impact attenuator modeling.

Elements which share nodes with the deleted element become “crashfront” elements and can have their strengths reduced by using the SOFT parameter (Boria and Belingardi, 2012) with TFAIL greater than zero.

With the single shell layer approach, the laminate lay-up can be defined by one integration point for each single ply with the respective ply thickness and fiber orientation angle. The card *PART_COMPOSITE permits to define this easily, defining the laminate thickness as the sum of each individual layer with the proper fiber orientation. Once all single layers of the shell element fail, the whole element is eroded, and it simply disappears from the calculation. Under-integrated shell elements of the Belytschko-Tsai type (ELFORM = 2) with the stiffness-based hourglass control (IHQ = 4) were used for the modeling. Such choice was justified by the negligible of the hourglass energy, that is less than 1% of the total energy.

The inter-laminar failure can be captured using a solid approach with cohesive elements. In particular *MAT_COHESIVE_MIXED_MODE model was used, that includes a bilinear traction-separation law with quadratic mixed mode delamination criterion and a damage formulation.

A “rigid wall planar moving forces” card with a finite mass of 300 kg and an initial velocity of 7 m/s was adopted for the impact attenuator. Master-surface to slave-node and self-contact between the impact mass and the nodes of the sacrificial structures and on the structure, respectively, were defined. As regards the boundary conditions, the same used for the real test were implemented on the numerical model.

Results and Discussion

Fig. 17 shows the impact attenuator before and after impact. A progressive crushing with the deformation confined at impact wall was observed.

The signal obtained by the acquisition was filtered with a CFC60 filter in order to appreciate the deceleration versus time trend more accurately (Fig. 18). The integration of the signal one and two times permits to obtain information about variation of velocity and crushing in time. Table 2 summarizes the principal crushing parameters, such as the effective initial velocity, the total impact time (T), the final stroke (δ), the average deceleration (d_{av}), the average load (F_{av}), and the absorbed energy (E_{abs}). The impact duration is the instant of time from the beginning of the crash to the moment when the velocity vanishes. The average deceleration is obtained from:

$$d_{av} = \frac{1}{T} \int_0^T d(t) dt, \quad (1)$$

where $d(t)$ is the progression of deceleration in time. The absorbed energy corresponds, instead, to the area under the load-shortening diagram.

Comparing the dynamic results with the static ones (Fig. 19), previously acquired, it is clear a loss of absorption capacity at higher load speed, even if lower than that observed for simplest structures (Boria, 2016b). A similar behavior in terms of force versus displacement in both cases is evident, with the presence of three peaks due to the wall thickness change, but the static condition ensures a greater capacity of energy absorption respect to the dynamic one. The reason may be due to three factors: the filtering of the

Figure 17 Attenuator before (A) and after dynamic test (B).

Figure 18 Raw data and filtered data for deceleration versus time.

Table 2 Crushing parameters for impact attenuator under dynamic load.

Effective initial velocity (m/s)	Total impact time (ms)	δ (mm)	d_{av} (g)	F_{av} (kN)	E_{abs} (kJ)
6.8	32	112	21.6	63.5	6.9

**Figure 19** Experimental data under static and dynamic conditions for the impact attenuator.

signal, a possible strain rate dependence of the coefficient of friction and a different friction coefficient for the crushing surfaces used in the two tests (Farley, 1992; Feraboli et al., 2007; Hull, 1991; Mamalis et al., 1997B).

A comparison between numerical and experimental results was conducted using both shell and solid modeling. Fig. 20 shows such comparison in terms of load versus displacement curves under dynamic conditions. The trend highlights a good capability to capture the experimental crushing process of such structure, even though the complexity and heterogeneity of the CFRP composite material used. Such correspondence is also evident in the final crushing shape. Fig. 21A shows how the use of solid modeling can reproduce the sharp break of the laminate in a specific zone of the impact attenuator, while Fig. 21B shows that by using shell elements it is also possible to reproduce the flexion of the straighter wall under axial compression. The combination of solid and cohesive elements allows to reproduce some inter-laminar fracture phenomena that are not reproducible by using shell modeling. Unfortunately, a better crushing replication involves an increase into computing time, often not acceptable for complex systems.

**Figure 20** Force versus displacement diagram varying numerical modeling.

Figure 21 Experimental versus numerical deformation using (A) solid and (B) shell modeling.

Conclusions

In this article, the main crashworthiness aspects to consider during the design of an impact attenuator were presented. In particular, the attention was focused on two different materials, conventional and composite, particularly widespread into structural components. Their usage for specific attenuators was analyzed both experimentally and numerically.

Initially, a new impact attenuator design for a racing car, based on an aluminum sandwich structure was presented. Experimental test and numerical simulations of the axial dynamic crushing of such truncated structure were carried out. The results showed that the designed impact attenuator met the criteria for energy absorption, as stated by FSAE Rules, during the physical crash testing. As expected, the final deformation was characterized by plastic buckling with a series of folds that proceed from the top to the bottom of the impact attenuator with a progressive crushing. Despite the simplification adopted, the numerical model reproduced sufficiently well the crushing. A more precise numerical representation could better copy final deformation with a consequently growth of simulation times. Therefore, the numerical modeling procedure outlines in this work could be used with confidence for designing the proposed lightweight impact attenuator, using such thin-walled sandwich structure.

After, the efforts for the lightweight design and crash analysis of a specific CFRP, the frontal impact attenuator for a Formula SAE racing car were presented. A comparison with numerical modeling was done, both in terms of micro- and macro-mechanical approaches. In both cases the FE models were able to reproduce sufficiently well the crushing phenomena, despite the complexity and heterogeneity of the CFRP material used. Therefore these methodologies adopted have proven themselves accurate enough to design a specific impact attenuator made of conventional or composite material under dynamic axial loadings.

Acknowledgments

The author wishes to express her appreciation to Prof. Giovanni Belingardi, Ing. Alessandro Scattina, Ing. Jovan Obradovic of Politecnico di Torino for their support and advice. Moreover, the availability of Picchio SpA drop tower used for the experimental dynamic tests is gratefully acknowledged.

Introduction

All-terrain vehicles (ATVs) and snowmobiles have become major forms of transportation on finished roads, dirt trails, and rough terrain. Both types of vehicles have been used for recreational and occupational purposes with increasing frequency. Currently, an estimated 25 million persons ride ATVs and 10 million persons ride snowmobiles annually in the United States and Canada. Of the 11 million ATVs and 1.2 million snowmobiles registered in the United States, many have been adapted for a variety of recreational and occupational uses and environments. Use in occupational environments include industry sectors, such as agriculture, logging, search and rescue, firefighting, land management, land exploration, oil and gas, mining, parks and recreation, hunting, law enforcement, military, field research, and others (Lagerstrom et al., 2015). It has been reported that 80% of the units sold, both ATV and snowmobiles are intended for recreational purposes and approximately 20% are used for occupational purposes.

In some parts of the world, such as Australia, ATVs may be referred to as “quadbikes,” where some 60,000 units are used heavily in agricultural operations. More recently, the introduction of the utility terrain vehicles (UTVs) provides users with a design alternative commonly referred to as side-by-side (SXS) vehicles, which allow riders to ride adjacent to each other on bench- or bucket-type seats. Conversely, ATVs require the rider to straddle the seat. The two distinctly different designed units comprise the larger group often identified as off-highway vehicles (OHVs) or recreational off-road vehicles (ROVs) or off-road vehicles (ORVs).

The popularity of ROVs and snowmobiles continue to climb among global consumers. Worldwide sales of ATVs/quadbikes were estimated to be more than 200,000 in 2014 while the more popular UTV sales reached 400,000 in 2016. More than 120,000 snowmobiles were purchased worldwide in 2018. The ROVs show increasing popularity and utility by meeting a variety of individual, group, and/or business transportation needs. The ROV transportation market has been estimated to reach \$8 billion in sales by 2024. The annual North American economic impact of ROVs and snowmobiles is estimated at \$66 billion and \$28 billion, respectively. These economic impacts are very positive to local communities by increasing tourism related lodging and restaurant services in addition to fuel, permits, and tax revenues.

ATVs/ROVs

ATVs arrived in the United States in the early 1970s. The vehicles had immediate application in the agricultural sector and quickly became appealing to recreational riders. The first models were three-wheeled designs with low inflation balloon tires, light weight, and steered with motorcycle handlebars. Sales soared, as did vehicle-related injuries and fatalities, catching the attention of many consumer groups. In the early 1980s, the industry manufacturers negotiated with the Consumer Product Safety Commission (CPSC)

Figure 1 Four-wheeled ATV. Source: Photo provided by Quadbar Industries.

to cease production of the three-wheeled units and were replaced by the more stable four-wheeled vehicles (quadbikes) known and used today (**Fig. 1**) ([GAO, 2010](#)). Many three-wheeled units still exist and continue to be used despite the known risks. The ATV industry continued to evolve designs resulting in the latest UTVs, also named recreational utility vehicle (RUVs), SXS, and side-by-side-vehicles (SSVs). The UTVs and ATVs are similar in some regards but differ in fundamental design attributes, such as a steering wheel instead of a motorcycle handlebars, foot pedals in place of hand levers for throttle and brake control, and bench or bucket seats replaced the traditional ATV straddle seating. A significant difference in stability stems from a wider frame design with a resulting stability that is less, or not affected by, passenger movements, which was not the case with the relatively more unstable ATVs. In addition, ATV passengers presented an increased risk for loss of control due to the added weight above the center of gravity, causing additional instability. Passengers on ATVs are not recommended as the ATV was designed for single rider use only.

Sales of UTVs have been nearly twice that of ATVs due to their enhanced stability, perceived safety, load capacity, and ability to carry more than one passenger. ATVs and UTVs now come in a variety of sizes and power ranges to accommodate user preference. The ATV sized for children are designed much smaller, weighing approximately 90 kg (200 lb) and are powered by a small 50 cc motor. Today's adult-sized ROVs may weigh as much as 680 kg (1500 lb) and are capable of speeds of more than 120 km/h (80 mi/h).

Epidemiology of ATV-Related Injury and Fatality

The CPSC started investigating ATV accidents in 1982 and has since then investigated more than 15,000 ATV/ROV-related fatalities. Major risk factors associated with loss-of-control events, collisions, injuries, and fatalities included consumption of alcohol, not wearing a helmet, riding on paved roads, carrying a passenger, excessive speed, riding up hills, down hills or cross-slope, and/or striking stationary or mobile objects. ATV/ROV sales peaked in the mid-2000s, as did injuries and fatalities. It has been estimated that more than 400,000 ROV riders are injured each year and 100,000 emergency room visits are associated with ROV accidents and loss-of-control events ([CPSC, 2019](#)). The growing use of UTVs has slowed the number of ROV fatalities resulting in a frequency ratio of 1:4, UTV to ATV (quadbike). The UTVs have wider wheelbases and are equipped with seatbelts and a roll-cage that creates a survival space, thus, providing greater protection for the user in the event of a rollover accident. Data compilation on UTV safety and risk factors continues to grow. In recent times, a great number of product recalls have occurred due to safety concerns, such as loss of control, fire, and burn hazards. For example, in 2017, the John Deere Crossover Gator utility vehicle was recalled due to a crash hazard. It was discovered that the steering shaft could separate from the steering-rack assembly resulting in loss of control. The recall affected 68,000 UTVs. The CPSC continues to investigate all ROV-related fatalities and provides publicly accessible reports to keep consumers and other interested parties informed. As the statistical safety data grow, more information about the risk factors associated with ROV injury and fatality becomes available.

Safety Measures

Rider Practices and Training

There exists an overriding belief that operating ROVs is risk interactive. This belief presumes that the operator can both increase and decrease the risk for loss-of-control events based upon choices and actions within his or her control. As a consequence of this belief, great emphasis has been placed on rider education and preparation through training and education to reduce risks and hazards associated with the vehicle's operation.

The ATV (quadbike) manufacturing industry agreed to provide rider training and formed the ATV Safety Institute (ASI) as the educational arm of the Specialty Vehicle Institute of America in the 1980s. The agreement between the ASI and CPSC required that with each new ATV sale, that the purchase be accompanied with subsidized access to the ASI ATV safety RiderCourse. The new owner would be able to use the worldwide web to identify a trainer in his or her area and procure the training, essentially free of charge. The high-quality RiderCourse was to be taught by ASI certified trainers and included a 5-h, hands-on field course to effectively enhance rider awareness of associated hazards and risks, practice skills for safer riding, reduce risks, and prevent loss-of-control events. The RiderCourse ATV safety training includes information and experiential learning about rider personal protective gear, pre-ride check, starting, stopping, turning, climbing grades, descending grades, cross-slope safety, as well as managing obstacles.

In 2017, the ASI reported that about 1 million riders had completed the training. Numerous user groups, both recreational and occupational, have advocated and even required the ASI RiderCourse for their members. In the United States, many private sector employers and government agencies require the RiderCourse before initial use and as a refresher training every 3 years for workers that use the vehicles in their job duties, and the number of employers requiring the RiderCourse training is increasing. However, very few studies support the success of rider training and additional research is warranted for the evaluation of training effectiveness. At this time, the effect of ATV safety training on post-training riding behaviors is unknown.

A large number of ATV youth-riding organizations and other types of user groups have produced an array of educational materials and training experiences to increase the safety awareness related to ROV selection, rider gear, and vehicle use. Many agricultural-focused education and research units produce ROV safety information sheets and other forms of handout materials that are disseminated person-to-person, by mail, and on the worldwide web. Most of the safety messaging appears to have been developed with the basic ASI tenants and content. Messaging commonly includes the following key items:

1. Always wear a helmet
2. Take the ASI hands-on training RiderCourse
3. Refer to the owner's manual for safe operation and sizing
4. Complete a pre-ride vehicle check before every use
5. Wear the proper riding gear—gloves, long-sleeve shirt, full-length pants, boots above the ankles, face shield or goggles, and three-fourths or full-face helmet
6. Choose the age appropriate vehicle for the rider
7. One rider only
8. Ride on permitted trails or lands only
9. Do not drink alcohol

Newer web-based interactive training is also available through a number of organizations as well as the ASI. The common goals of web-based ASI training and other ROV web-based training is to increase awareness of the risks and hazards associated with ROV use and to offer information about methods to mitigate known risks and hazards. Another major goal is to encourage new riders to take the ASI hands-on RiderCourse for the experiential learning.

Vehicle Design

Design improvements have been at the center of the ROV evolution and revolution. The migration from three-wheeled to four-wheeled ATVs and now to UTVs with rollover protection and seat belts have been major design changes driven by the demand for safer vehicles. Two different organizations developed separate voluntary safety standards for ROVs. The Recreational Off-Highway Vehicle Association (ROHVA) co-developed ANSI/ROHVA 1, American National Standard for Recreational Off-Highway Vehicles, and the Outdoor Power Equipment Institute (OPEI) co-developed ANSI/OPEI B71.9 (2012), American National Standard for Multipurpose Off-Highway Utility Vehicles. The two industry-based standards have been progressive and evolved with the growth and responsibility of the industry. The CPSC sponsored the 16 CFR Part 1422, Requirements For All Terrain Vehicles, that was adopted in 2008 to address consumer protection, information, labeling, recreation, and recreation areas pertaining to ATVs and ROVs and the import restriction of three-wheeled models.

In 2014, the CPSC proposed a design standards rule for ROVs to address continuing safety concerns. The rule did not pass, therefore leaving in place the current ANSI/ROHVA 1 for recreational ROVs and ANSI/OPEI B71.0 for utility-oriented ROVs voluntary standards (CPSC, 2014). These standards address vehicle design, configuration, and performance aspects of ROVs. Specific requirements exist for accelerator and brake controls, service and parking brake/parking mechanisms, lateral and pitch stability, lighting, tires, handholds, occupant protection system, labels, and owner's manuals. The CPSC advocated for enhanced standards related to lateral load shift stability, tilt stability, dynamic stability, steering systems, seatbelt reminder systems, and occupant retention systems. The CPSC had proposed a speed limit of 15 mi/h, if the seatbelt was not fastened. The belief was that such a limit would motivate the operator to buckle-up. Standards will continue to evolve in response to social, political, technological, and economic forces. In the meantime, retrofitting ATVs/quadbikes with rollover protective devices is a less expensive design change that has promised for reducing fatalities associated with rollover accidents.

Rollover protection systems (ROPS) or crush protection devices (CPDs) became increasingly popular in New Zealand and Australia over the past 2 decades. A number of products were developed with variations in design and materials coupled with rebate programs to incentivize retrofitting vehicles already in use. Under test conditions, the ROPS were estimated to reduce

Figure 2 ATV fitted with a Quadbar. *Source: Photo provided by Quadbar Industries.*

crash-related fatality from rollovers by approximately 40%. The ROPs, when attached to the ATV, is fitted to the vehicle behind the rider creating a survival space in the event of a rollover thus, preventing crushing by the vehicle. In 2017, New Zealand authorities recommended that ROPs be required for all quadbikes. The ROPs have not had the same level of acceptance in the United States (Fig. 2).

Laws

Various laws, statutes, rules, and regulations are pervasive, vary by state, county, or city and generally require registration at a minimum. Many states allow ROVs on roadways used by automobiles, trucks, and other vehicles. Some states allow licensing equal to other vehicles and permit full access to most road surfaces and conditions except freeways or interstate roadways.

Safety-related laws are highly variable and may include mandatory helmet use, safety education certification, age restriction for operation, headlamps, brake lighting, turn signals, passenger prohibition, width, weight and displacement limits, wheel/rim diameter limits, tire pressure requirements, wheel base requirements, braking capability, and reflectors/reflectorized material requirements. The legal landscape will continue to evolve as ROV users pressure policy makers to open access to roads and public lands while consumer safety groups and others campaign for greater restrictions to reduce injuries and save lives.

Vehicle Star Rating and Fit for Use Standards

A great deal of high quality research on ROV safety has been performed in Australia and New Zealand leading to a novel system for vehicle rating based upon its intended use (Grzebieta et al., 2015). The ATV or quadbike and SSV, "Vehicle Star Rating" (VSR) system, was developed by scientists and engineers working in the Transport and Road Safety (TARS) research center at the University of New South Wales. The research team crash-tested vehicles under various conditions to assess the probability for operator survival, considering in part, the survival space dimensions and the potential for injury. Based on the results of the performance tests, the team developed a rating scale that ranged from 0 to 5, with "5" assigned to those vehicles with the lowest risk of a rollover and superior safety performance. A rating of "0" indicates, in part, that the vehicle has no survival space and rollover results indicate high impact forces, whereas those vehicles with an ROPs, seat belts (3 point), and adequate survival space may warrant a rating of "3."

Authors of the VSR strived to reduce ROV related injury and fatality by properly classifying vehicle safety based upon intended use. The VSR applies to both the workplace and recreational environments thus increasing the number of informed consumer

choices in the selection of appropriate vehicles for a user's job or recreational needs. The TARS team also believes that the VSR will create competition among vehicle manufacturers to improve safety and seek higher ratings through enhanced design and technological changes and reduce the training and education burden currently on the operator.

Conclusions

There are known risks and hazards associated with ROV use, either recreationally or occupationally. The ROV epidemiologic data are overwhelming in identifying known risk factors associated with loss-of-control events and resulting injury and/or fatality. At minimum, riders should always wear a helmet and avoid alcohol use, if intending to operate an ROV. Safer use of ROVs may be achieved through training and education, engineering designs that maximize stability and safety performance, ROPs, regulatory protections through mandated standards, and selection of the appropriate vehicle for its intended use.

The evolution of ATVs to UTVs appears to be an effective step for ROV safety. The development of structural rollover protection, operator and passenger restraint systems, and enhanced stability, has proven to be positive steps in ROV safety to reduce the number of injuries and fatalities. The implementation of the VSR has only begun. In the long term, safety professionals are hopeful that the VSR "fit for use" system will become the consumer standard for ROV selection. It is also believed that the industry will respond by enhancing product design, engineering, and safety to provide enjoyment to riders with vehicles that meet the needs of a growing number of employers who use ROVs in their work practices.

Snowmobiles

Snowmobiles made their arrival in the United States in the early 1900s as motorized sleds. The modernized snowmobiles did not appear until the 1950s and quickly became immensely popular in the 1960s with the production of the lightweight, newly designed Ski Doo. The vehicle became a sensation and other manufacturers emulated the basic design of open cockpit, straddle seating, handlebar steering, and one or two seat versions. Annual sales skyrocketed peaking at an estimated 500,000 units sold in 1971. The highly versatile units found great success among the recreational users with adaptations to a number of work environments. By the early 2000s, four major manufacturers dominated the market. In 2018, an estimated 127,000 snowmobiles were sold worldwide with over 2 million registered units in the United States and Canada alone. Modern snowmobiles are designed with larger, more powerful engines ranging from 400 to 1000 cc, weighing nearly 272 kg (600 lb), and reaching speeds of 240 km/h (150 mi/h) with specialty machines capable of achieving speeds greater than 320 km/h (200 mi/h). Snowmobiles may be ridden on nearly any type of snowy terrain and are classified as ORVs as well. Their popularity adds significantly to many local economies.

It has been estimated that approximately \$2,000 per season per rider is spent (e.g., lodging, fuel, food, clothing, and equipment) in many areas with a continuing upward trend expected. The industry employs more than 100,000 individuals in North America generating in excess of \$30 billion of business in the United States and Canada. Snowmobiles have been essential vehicles for transportation of persons, supplies, and emergency response in snowbound areas throughout the most northern and southern latitudes. They have been adapted for many occupational uses, such as scientific exploration, fieldwork and sampling, materials and supplies transport, search and rescue, emergency response, enforcement, hunting, surveying, ranching, public utilities, winter sporting events, and user and passenger transportation from site-to-site when other vehicles are not able to perform. There are more than 3000 snowmobile clubs and organization worldwide. The snowmobile market is expanding into Europe and Russia, generating an estimated \$5 billion impact annually into the new sectors.

Epidemiology of Snowmobile Injury and Fatality

It has been estimated that more than 10 million people enjoy snowmobiling each year in North America where the average enthusiast rides her/his snowmobile 160–240 km (100–150 mi) per day trip and approximately 2012 km (1250 mi) per season. As snowmobiles became larger, heavier, and faster, there has been significant injury and fatality among the user population. Approximately 3% (>4000) of snowmobile riders in British Columbia, Canada, experience injuries and 36.5/100,000 are killed in events associated with vehicle use and loss-of-control events. In North America alone, it has been estimated that over 14,000 snowmobilers suffer accident-related injuries and 200 persons die annually. The estimated fatality rate in North America is 1.6 fatalities for every 100 million miles traveled $[(200 \text{ fatalities/year}) / (1250 \text{ miles traveled/rider/year} \times 10 \text{ million riders})]$. Injury events most commonly have been rollovers, collision with fixed or mobile objects, and submersion in lakes. Males are killed at twice the rate of females. Those riders between 21 and 30 years are the highest at-risk age group. Eighty percent of fatalities occurring in Canada happen off trail. Alcohol is the leading cause of loss-of-control events resulting in injury or death. Additional risk factors include not wearing a helmet, excessive speed, lack of experience operating a vehicle, lack of training, lack of good judgment, and operator error. For example, it takes at least 16 m (52 ft.) to stop a snowmobile traveling at 25 km/h (15 mi/h) and 83 m (272 ft.) for a vehicle traveling 72 km/h (45 mi/h), thus making accurate judgments about stopping are very important. Head injuries are the leading cause of death from snowmobile accidents. Common injuries include concussions, spine injuries, extremity fractures, lacerations, contusions, internal organ damage, and multisystem trauma. Extremities are the most common body part injured followed by the head and face, soft tissues, thoracic, spine, abdomen, and pelvis. Other types of injuries may occur and include burns, frostbite, hypothermia, and noise-induced hearing loss. Frostbite and hypothermia are significant risks as hazards are associated with the cold climate conditions. Snowmobiles make significant noise, and concerns have focused on preservation of quiet surroundings and protection of the riders. Hearing loss has been associated with long-term snowmobile exposure and the lack of hearing protection.

Safety Measures

Rider Practices and Training

The International Association of Snowmobile Administrators (IASA), the American Council of Snowmobile Associations (ACSA), and The International Association of Snowmobile Manufacturers Association (ISMA) support enhanced user awareness for snowmobile safety through an education program named, “Safe Riders.” This program has a number of emphasis points: no alcohol when riding, know your abilities, don’t exceed your abilities, know your machine’s capabilities, don’t exceed your machines capabilities, know your riding area, get a map, talk to local folks, learn as much as possible from organized rider groups, keep your machine in top running condition, complete a pre-ride check, follow the rules, take great care when crossing trails or roadways, dress properly, layer up, wear a helmet and goggles, gloves and boots, take a friend or ride in a group, and file a plan. Other key safety points include staying alert, becoming aware of darkness and low light conditions, be aware of water and possible ice failure, and unique mountain risks, hazards, and added dangers. If riders are interested in mountain trails and/or terrain, it is recommended to secure avalanche training when snowmobiling in mountainous areas and/or backcountry areas. The Safe Riders program also emphasize on caring for the environment and advocates staying on marked trails to preserve the habitat. For example, Minnesota maintains more than 200,000 miles of groomed trails for snowmobilers. This training program also includes training on the use of hand signals for important and common communications necessary to convey to other riders, such as stop, start, right and left turn, slowing, oncoming sleds, flowing sleds, last sled, and take care of the trail.

The Safe Riders pledge includes the following concepts and practices: I will never drink and ride, I will drive within the limits of my machine, obey the rules, be careful crossing roads and trails, keep my machine in top shape, complete a pre ride check before each ride, wear a helmet and appropriate gear, let my family or friends know my planned route and time schedule, and treat others and the out-of-doors with respect.

The American Pediatric Association has published recommendations similar to Safe Riders and added another policy warning against towing others on saucers or tubes. The ISMA also recommends using a global positioning system (GPS) when riding to ensure accurate navigation and signaling for emergency purposes.

Design

The Snowmobile Safety Certification Committee (SSCC) recently updated its safety standards for testing and design specifications in 2018. The industry organized and collaborated with the Society of Automotive Engineers (SAE) to create guidelines since 1970s. The current manufacturing and testing standards are voluntary and followed by manufacturers who sell in North America. The standards result in SSCC Certification Labeling on snowmobiles. Current SSCC certification requires adhering the SAE standard ICS1000 (Recreation Off-Road Vehicle Product Identification Numbering System) and its 18 subsections which cover definitions, lighting systems, brake systems, throttle controls, runaway prevention system, electrical systems, drive mechanisms, transmission guards, heat shields, fuel tank, operational sound levels of 78 dBA maximum, rider shields, handedness, occupant support system, capacity,

and vehicle classification. In addition, Class I type machines are designated as competitive whereas, Class II are designated for children. The standards include detailed testing requirements, such as acceleration, braking distance, and quality assurance. The voluntary standards have continued to evolve in response to political, economic, social, and technological forces. Vehicles sold outside of North America may not adhere to the same standards.

Laws

The rules, regulations, ordinances, and laws pertaining to snowmobiles are highly variable by region, state, county, and/or municipality. Half the states in the United States and all provinces of Canada have laws that regulate aspects of snowmobile ownership. For example, Alaska classifies snowmobiles as OHVs and has extensive laws governing their use. However, most jurisdictions require registration at minimum, and some states allow licensing similar to cars and require plates and OHV decals. Few states require helmets for operators and/or passengers whereas British Columbia requires helmets for both. Some states also require liability insurance for OHVs. Many groups are in favor of progressive licensing, restricting riding activities, times, and conditions until a youth becomes an adult, and a number of states legislate minimum age limits for riders ranging from 10 to 16 years. In addition, safety education certification is required in some jurisdictions to operate OHVs.

Some of the other variable rules, regulations, ordinances, and laws address traveling on roadways. In some states, roadway travel may require a valid driver's license and some allow snowmobiles on roads when traditional vehicles are not capable of operation due to snow and ice. In addition, some areas allow snowmobile travel alongside roadways with restrictions. While some states have speed limits, other states allow riders greater latitude by requiring "safe and reasonable" speeds adjusted to variable conditions. It is likely that laws will continue to change as consumers wish to expand their access to public lands, communities seek to relax restrictions on roadways, and agencies and other rider protection-oriented groups seek to strengthen safety laws to reduce the incidence of injury and fatality.

Conclusions

Snowmobiles are popular form of transportation enjoyed by many for recreational purposes as well as for essential workplace needs. Epidemiologic data have strongly related known risk factors for loss-of-control events to resulting injury or fatality. Further, sales of snowmobiles are rising as markets expand from North America to worldwide locations and as a result, injury and fatality are expected to rise. A few key safety messages remain consistent and strong:

1. Don't drink alcohol and ride
2. Don't drive too fast
3. Know your limits
4. Know the limits of the snowmobile
5. Wear the appropriate gear
6. Prepare for emergencies
7. Plan your ride
8. Let others know your plan
9. Follow the laws

The industry has collaborated uniquely to support safety and machine performance. Design and testing standards will continue to evolve. Safety training is offered by a great number of organized groups that consistently teach the tenets of the Safe Rider program. Countries, regions, states, and communities have implemented legislation to manage snowmobile use, and in many cases, the aspects of safety.

Introduction

According to 2011–16 Fatality Analysis Reporting System (FARS), approximately 2.6% of fatal crashes in the United States involved vehicle-related faults as a primary contributing factor. Previous studies indicate that a majority of technological defects are identified during inspection of wearable parts such as lights, tires, and brakes. However, the proportion of vehicle failures that can be contributed to crash occurrences was revealed to not have changed fundamentally since the 1970s. In the United States, the National Highway Traffic Safety Administration (NHTSA) suggests that each state implement a program to inspect all registered vehicles (annually or biennially) to guarantee that unsafe vehicles are taken off the roads. Nonetheless, it is critical to acknowledge that studies lack any correlation between crash rates and inspection programs related to vehicle component failure. When legislation restricted the NHTSA's authority to reserve highway funding in 1976, the number of states with vehicle inspection programs has decreased. As of July 2015, only 16 states continue to implement the recommended regular safety inspection program.

Safety inspection regulations in Canada vary from province to province. The Ministry of Justice in Canada provides a detailed regulation in the document "Motor Vehicle Safety Act" (The Ministry of Justice, Canada, 2019). According to the directive 2014/45/EU of the European Parliament and of the Council on "periodic roadworthiness tests for motor vehicles and their trailers and repealing Directive 2009/40/EC" (issued on April 3, 2014), "all member states need to carry out periodic safety inspections for most types of motor vehicles with designed speed exceeding 40 kmph/25 mph" (Official Journal of the European Union, 2014). In Australia, each state or territory preserves the authority to set its own safety inspection regulations. Poorly designed and old vehicles contribute significantly to traffic deaths in the Asian countries. Automobile safety inspection programs are not effectively regulated through design standards or maintained through mandatory vehicle inspection schemes (World Resources Institute, 2018).

While vehicle safety inspections could likely decrease the possibility of crashes, the degree of the reduction is difficult to quantify. Earlier studies do not implicate that safety inspection programs have zero effect on the reduction of crashes; however, the results are inconclusive. Additionally, international studies were unable to determine a relation between inspection programs and crash rates. Conclusively, there is an absence of research on the effectiveness of vehicle safety inspections on crash reduction. This study provides a short overview on this topic with inclusion of research directions and future scopes.

Literature Review

Limited research has been conducted on the effects of automobile safety inspection programs. One earlier study (conducted in 1999) recorded the results of several earlier studies. Using various sources, the previous studies (conducted before 1995) displayed contradictory findings about the significance of automobile safety inspections. Using panel data from all US states during the years of 1981–93, this study found no evidence that inspections considerably decreased injury or fatality rates. The Federal Motor Carrier Safety Administration has revoked an arrangement for commercial drivers to lodge inspection reports if vehicle deficiencies or flaws are not obvious. Regardless, the regulation does not affect the responsibility of drivers to report any deficiencies or faults to the motor carrier on the condition of a vehicle.

The United States Government Accountability Office (GAO) analyzed the costs and safety benefits of operating state vehicle safety inspection schemes, obstacles faced by states in administering these schemes, and tasks that could be taken by NHTSA to assist states with these initiatives (US GAO, 2015). The study evaluated state data and data from NHTSA (2009–13) for crash trends

attributable to the failure of vehicle components; analyzed studies that reviewed relations between safety examinations and outcomes; and interviewed inspection representatives from 15 states. The GAO also interviewed representatives from five states that discontinued their safety inspection programs since 1990. The officials representing the five states and the District of Columbia cited the lack of concrete evidence to rationalize the efficiency of the system to conserve financial resources as one of the major reasons for eliminating the program. The study concluded that state officials adopted different criteria and chose not to include technological advances in their inspection systems, likely decreasing their inspection program's safety benefits. However, the study found that the states support using LED brake lights to enhance safety versus the conventional one. Similarly, the states have established more rigid system guidelines for inspection stations to be implemented to diminish fraudulent behavior such as fingerprint scanners for proper identification until inspections are carried out. The states have also begun to plan workforce reports, introduce more rigorous program guidelines, and develop digital information systems while addressing the challenges. The study suggested that to improve aid to states concerning the periodic motor vehicle inspection policy, there is a strong need to direct the NHTSA Administrator to develop and manage a communication and management framework with states to respond to questions from officials of the State Security Inspection Program and relay appropriate vehicle inspection data.

Vlahos et al. (2009) used Pennsylvania vehicle registration data. The researchers found that the failure rate of safety inspection for light-duty vehicles is between 12% and 18% (well above the often-cited rate of 2%). Older vehicles (more than 3 years old or having mileage greater than 30,000 miles) usually show higher rates. The evaluation of the new vehicles (less than or equal to one year old) shows that the failure rates of these vehicles are over zero. It is important to note the newer technologies, safer systems, and driver assistance make the vehicle fleets safer over the past few years. The current trend shows that inspection failure rate does not appear to be declining soon. This study also displayed that correct inspection data are limited, and vehicles are frequently inspected inaccurately. A similar analysis was conducted in North Carolina ([North Carolina General Assembly Program Evaluation Division, 2008](#)).

Das et al. (2018) explored 67,201 crash-related vehicle complaint reports from NHTSA database. This study found that major vehicular defects are associated with air bags, brake systems, seat belts, and speed controls. In a follow-up study, Das et al. (2019) conducted a statistical significance test to establish the efficacy of vehicle safety systems dependent on the existing states with and without safety inspection. The study used NHTSA automobile complaint data and FARS databases to evaluate the efficacy of regulatory vehicle safety components in different US states.

It is challenging to examine the advantages and disadvantages of state inspection programs, and state program officials often face challenges in program operations. However, these programs do ultimately enhance vehicle safety. It is obligatory of the administrator of NHTSA to establish and manage open communication with these state programs to relay important information and assist the states regarding the motor vehicle inspection guideline. With these enhancements, these programs could have more of an impact on improving vehicle safety in their respective states.

State Laws and Effectiveness Measure

Vehicle Inspection Program

In the United States, researchers are limited in determining the association between crash occurrences and vehicle-related failures by the lack of data. FARS data only provide fatality-related crash data at a national level. Due to the absence of national crash data with other severity levels, the crash rate comparison for inspection programs is hard to attain. Some states attribute the elimination of these programs. However, states generally do not accurately consider the costs of overseeing and managing these programs. The operating costs of inspection programs are entangled with additional programs, so determining the expense of vehicle inspection operation is not entirely possible. Also, there is typically a fee associated with safety inspections, which returns money to the state, but the amount varies between states. These funds are allocated to where each state deems fit before they are given to the inspection program. Currently, there are no states that have federally funded inspection programs ([US GAO, 2015](#)). Without properly identifying the operational costs of vehicle inspection programs, states cannot determine whether the costs of these programs outweigh the effects on crash rates. Because of the lack of evidence proving the effectiveness of the program or saving financial resources, some states have eliminated their programs.

States with inspection programs require information and guidance from the NHTSA to improve their program operations. As innovative vehicle technologies emerge, states need guidance in integrating these technologies as well as adding new requirements to their inspection programs. However, the NHTSA does not have a definite answer regarding the effectiveness of automobile inspection programs.

Table 1 displays which states have different types of automobile safety inspection regulations (i.e., annual, biennial, and random). As shown in **Table 1**, the following states have some sort of automobile safety inspection regulations: Delaware,

Table 1 Automobile inspection programs by state

Duration	States	Description
Annual	HI, LA, ME, MA, NH, NY, NC, PA, TX, VT, VA, WV	Require an annual vehicle safety inspection (LA: in areas where emissions inspections are needed)
Biennial	DE, LA, MO, RI	Require a biennial inspection (LA: in areas where emissions inspections are not needed)
Random	UT	Random roadside inspections

Figure 1 Vehicle inspection requirement by state.

Hawaii, Louisiana, Maine, Massachusetts, Missouri, New Hampshire, New York, North Carolina, Pennsylvania, Rhode Island, Texas, Utah, Vermont, Virginia, and West Virginia. A majority of the states have annual inspection programs and three states (Delaware, Missouri, and Rhode Island) require biennial inspections. Louisiana has both annual and biennial inspections based on the areas with emissions inspection requirement. According to the GAO report, Utah has random roadside automobile inspection programs. The NHTSA specified protocol outlines the minimum requirement for several important vehicles components such as tires, brakes, steering wheel, suspension system and wheel rotation or assemblies for safety inspections. This standard is applicable to all states with automobile inspection regulations (i.e., the states listed in [Table 1](#)). However, additional inspection requirements such as headlights, safety straps, horns, wiper blades vary based on the policies and regulations in each state ([US GAO, 2015](#)).

Fig. 1 shows the map of the United States with dark green squares indicating states that have some sort of inspection program. The light green squares indicate states with no automobile inspection program. As shown in **Fig. 1**, only 36% of the states has some sort of inspection programs.

Data Sources

FARS Data

The NHTSA has maintained the FARS database since 1975. During 1975–2017, there were 1,615,539 fatal crashes in the United States. The FARS database contains data from all 50 states, the District of Columbia, and Puerto Rico; it has information for 1.6 million fatal crashes in the United States. The major sources of this comprehensive database include police recorded crash reports, hospital entries and medical reports, emergency services, registration files, and state department of transportation records. The FARS database contains a comprehensive list of data elements in each fatal crash by characterizing crash event, involved vehicles and peoples, and event hierarchy. FARS data are a vital source for many researchers to understand the key contributing factors that lead to a fatal crash occurrence, such as roadway geometry, driver and vehicles, and ultimately working toward crash prevention.

NHTSA Vehicle Complaint Data

As an additional road safety improvement effort, the NHTSA maintains records of public provided complaints about vehicles, vehicle components, and transportation-related equipment. The database also contains vehicle and crash information to some extent. The data have been developed based on the complaints of vehicle owners or attorneys by several communication systems such as phone, fax, mail, or online submission. In these reports, the participants provide vehicle component failure information and describe the associated consequences for the failure. After receiving reports, Office of Defects Investigation analysts identify the failed component and complete the “specific component’s description” field. It is important to note that several records may exist for a single event or crash because there is a possibility of multiple failures in one event or crash ([Das et al., 2019](#)). Additionally, this database can provide insights on safety issues associated with vehicle models or components, identify safety trends for proper impact, track ongoing recalls, and order investigations for defects that may result in safety failure. The database developed till 2018 incorporates one and half million vehicle or vehicle component complaint reports in structured form with a wide list of variables. Around 8% of these reports involve fatalities or some level of injury. The complaints file contains all safety-related defect complaints received by NHTSA since January 1, 1995, as well as some incomplete rerecords for earlier years.

Das et al. (2019) applied a statistical significance test to this data to investigate the safety effectiveness of state-maintained vehicle inspections. The analysis used the “Cohen’s d” statistic to evaluate the differences in mean measures (complaints, complaint involved crashes, and fatal crashes from FARS) between the states with and without automobile inspection programs during the two time periods. This study conducted statistical significance test (using Cohen’s d measure) to determine the effectiveness of the vehicle safety inspection programs based on the states with and without automobile inspection program in place. The results from the vehicle complaint data showed that states with inspection programs expect a smaller number of monthly vehicle complaints and vehicle failure-related crashes than the states without safety inspection programs. This supports the claim that the mandatory vehicle inspection programs have a positive effect on safety. In contrary, the analysis of the FARS data showed no evidence on the positive effectiveness of safety inspection programs.

Future Scope and Research Direction

Further research concerning traditional methods such as regression modeling is required to examine the effectiveness of automobile safety inspection programs. Additionally, more advanced methods such as machine learning and deep learning can be applied to mitigate the research gap. Using innovative data source such as NHTSA vehicle complaint data is noteworthy. However, it is important to note that NHTSA may not receive all the vehicle complaints and so the results presented the recent study may not be comprehensive. There is a need for advanced analysis in reducing bias associated with the underreporting of these complaints. Furthermore, since the analysis using FARS data did not show any evidence of effectiveness of these programs, advanced tools such as machine learning models can be applied to reexamine the hypothesis of the effectiveness of the safety inspection programs using FARS data. Alternative data source such as General Estimates Systems (GES) can be used; however, precautions should be taken as the GES estimated values are not the actual counts like the FARS database. Additionally, severity specific analysis can be conducted. Moreover, several new data sources should be compiled to perform a comprehensive analysis on the effectiveness of automobile safety inspection laws. Future studies can explore the following datasets:

- **Exposure Data:** Vehicle miles traveled is the most commonly used exposure measure because it most directly captures exposure to crash occurrences. The Federal Highway Administration Highway Statistics publication provides annual estimates by roadway function class and vehicle type. The Bureau of Labor Statistics is a good source of employment-related data. The US Department of Commerce is a reliable source for gross domestic product estimates by state and year.
- **Department of Public Safety (DPS) Inspection and Citation Data:** State DPS authorities maintain roadside stop and citation data and as well the data related to the vehicle safety inspection. Inspection data are available by type of inspection certificate issued.
- **Crash Data:** State specific crash data can be beneficial in exploring the effectiveness of the automobile inspection programs. An alternative data source is GES.
- **Revenue Data:** Revenue data for the states can be collected from the state’s department of transportation and/or the comptroller of public accounts.

The evaluation of the safety inspection programs on fatal crashes is challenging because crash fatalities are relatively rare events in the context of the overall amount of travel; also, relatively few police reports attribute the cause of fatal crashes to vehicle component failure. Additionally, GES or state specific crash data can provide additional insight into the effect of inspection programs. Future studies can examine the disposition of the associated fees and the intended use of the funds for the states with automobile inspection programs. Research can also explore how similar services are funded in the other 34 states as well. Researchers can estimate revenue impacts by examining the reported proceeds in each of the identified funds, both in the aggregate and on a per capita basis.

Conclusion

Despite the belief that periodic inspection of registered vehicles can improve safety, the number of states mandating safety inspections dropped from a high of 31 in 1975 to 16 in 2015. It is widely believed that safety inspections can reduce vehicles with issues that may contribute to the improvement of roadway safety. However, research about the effects of these programs is inconclusive due to limitation of comprehensive databases. It is important to note that forms of automobile inspection such as annual and biennial only safeguard some key components of the automobiles. In many cases, these inspections are only able to identify a portion of potential automobile defects. Furthermore, the failure of inspectors to take a proper amount of care can result in ineffective safety inspection programs, which can create societal and economic loss. The costs of ineffective programs include costs related to inspection site visits, drivers’ time, inspection-related resources, and nonmandatory repairs that required for privately owned cars to pass the inspection. These costs vary based on each state’s supporting resources and density of inspection booths.

Safety inspection regulations in the countries outside of the United States widely vary. In Canada, the regulations vary from province to province. The European countries maintain safety regulation programs; however, the regulations differ in different countries. Each state or territory of Australia maintains its own safety inspection regulations. In Asia, automobile safety inspection programs are not effectively regulated through mandatory inspection programs.

Many state policymakers have questioned the effectiveness of automobile safety inspection programs. This uncertainty required a more robust scrutiny of the effectiveness of current inspection programs that will consider the inspection process by analyzing the

state of vehicles before they undergo the inspection rather than after it is conducted. The compelling findings of one of the recent studies demonstrated that safety inspection failure rates remain high, which calls into question why vehicle inspection regulations are not federally mandated like emission inspections.

The framework development and implementation of more robust data collection systems is the key to improve program efficiency by allowing for stronger oversight and improved management. The paper-based data system for inspection programs requires significant program oversight and enhancement. The system could be more efficient if it contained the functionality of electronic data collection and error checking. The fact of the matter is that few states have vehicle safety inspection programs at present, and even fewer states maintain electronic safety inspection records. Because of this, the insights on these programs are limited. More advanced data sources and analytical methods are necessary to mitigate this crucial research gap.

Biography

Dr Subasish Das is an Associate Transportation Researcher at the Texas A&M Transportation Institute (TTI). He received his Master of Science in Civil Engineering in 2012 and his PhD in Civil Engineering in 2015 both from the University of Louisiana at Lafayette. He has more than 10 years of national and international experience associated with transportation safety engineering research projects. His primary fields of research interest are roadway safety, roadway design and operation, mobility, machine learning, deep learning, and natural language processing. Dr Das is the author or coauthor of over 80 peer reviewed journal articles and research reports. He is also the author of the CRC Press book, *"Artificial Intelligence in Transportation Safety,"* which will be published in 2020.

Introduction

Although they attract enormous attention, commercial aircraft crashes are rare and when one takes into consideration the number of air travelers, the chances of death from air crashes are extremely small and even less when compared to other forms of mass transportation. There is a range of estimates out there that predicts the odds of dying as a plane passenger. According to Alexandre de Juniac, IATA's Director General and CEO, an individual would need to take a flight every day for 241 years before experiencing an accident with one fatality on board. Dr. Per Garder, Professor of Civil and Environmental Engineering at the University of Maine, estimates (based on 2016 data) that an individual, on average, would need to fly once a day for 29,000 years before succumbing to a fatal crash. Finally the US National Safety Council's analysis of US Census data puts the odds of dying as a plane passenger at 1 in 205,552. That compares with odds of 1 in 4050 for dying as a cyclist, 1 in 1086 for drowning, and 1 in 102 for a car crash. Evidence suggests one is far more likely to die driving to the airport than being involved in a deadly plane accident. Air safety is improving with each passing year, with a future trend that reflects fewer deaths relative to the total number of traveling air passengers.

There are several reasons why commercial aviation remains the safest mode of mass transportation and this article will explore what commercial aviation safety is. There are four basic categories of aviation: *general aviation* (civilian/private flying that excludes scheduled passenger airlines), *corporate aviation* (air transportation for company employees and executives), *military aviation* (used for aerial warfare), and *commercial aviation* (used for paid transportation of people and cargo). This article will discuss safety in relation to *commercial aviation* only.

Commercial aviation is a type of ultra-safe high-risk industry (USHRI), such as the nuclear and chemical industry, in which there is less than one disastrous *accident* per 10 million *events*. An *incident* is something that happened during the operation of an aircraft which could affect the safety of operation but which did not rise to the severity of an accident. An incident could include a crewmember not being able to perform a normal flight duty because of injury or illness, an in-flight fire, or a flight control failure. An *accident*, however, is an occurrence that involves some degree of injury or damage related to the operation of an aircraft. While there are different variations of the definition of an accident, International Civil Aviation Organization's (ICAO) definition is

the most widely accepted in the commercial aviation sector. According to ICAO, a *major accident* occurs when an aircraft is destroyed, there are multiple fatalities, or there is a fatality coupled with a substantially damaged aircraft. A *serious accident* occurs when there is either one fatality without substantial damage to an aircraft or there is at least one serious injury and an aircraft was substantially damaged. An *injury accident* occurs when there is a nonfatal accident with at least one serious injury and without substantial damage to an aircraft, and a *damage accident* occurs when no one gets killed or seriously injured, but an aircraft receives substantial damage. The reference *Commercial Aviation Safety* (Cusick et al., 2017) reviews some of the significant accidents and actions taken (design, technology, and legislation) that have shaped the current commercial aviation industry to create a safer world for air transport.

While the aircraft is the core of the aviation transportation system, the aircraft itself is just one part of a wider air transportation system that includes airline and airport operations, maintenance, crews, security, weather services, and the air traffic control system. So aviation safety encompasses each of the aforementioned components of the air transportation system. What follows is a review of safety hazards that are encountered in the aviation transportation system and how the aviation sector manages risk associated with these hazards.

Aircraft Safety

Safety is the primary consideration of aircraft manufacturers when designing an airplane, with design standards that are often more stringent than regulatory requirements. Each critical system has at least one backup if not more. Twin-engine jets, for example, are designed to safely take off, fly, and land even if one engine fails. The airplane structure is designed to withstand 50% more load than the greatest load an aircraft might face while in service. Manufacturers build damage-tolerant airplanes that are rigorously tested to ensure they meet or exceed design standards and certification requirements, with extra margins of safety built in case of an extraordinary emergency. Aircraft structures are subjected to rigorous static and fatigue stress tests. Static tests validate the aircraft's ability to carry loads that are far greater than any load that would be faced under operational conditions. Fatigue tests subject an airplane to up to three lifetimes of normal wear and tear to help validate its durability (Boeing, 2019). Testing a new airplane design can take many months or even years and are conducted in laboratories, wind tunnels, icing tunnels, on the ground, and during flight tests. Boeing's aviation safety home page provides additional information on all of the above in greater detail.

High-Lift Systems

To accommodate the transition from piston to jet engines, high-lift systems such as movable aerodynamic surfaces on wings were developed to increase and decrease lift as a function of phase of flight. The multielement slotted trailing-edge flaps provided the required higher drag and power settings, while the addition of leading-edge flaps resulted in greater safety due to better takeoff and landing performance and greater stall margins. Leading-edge flaps on jets extend the margin of safety to even lower speeds and permit takeoff and climb out margins similar to those in prop airplanes. Today's jetliners often incorporate two-position leading-edge slats to provide low-deflection setting for low-drag takeoffs, a higher-deflection position for landing at lower speeds, and better pilot visibility from a lower deck angle. Some designs incorporate the auto slat to its configuration to enhance safety and improve stall characteristics while providing additional maneuvering margin in the case of a wind-shear encounter.

Stopping Systems

A number of safety improvements have taken place over the years in aircraft stopping systems. They include antiskid, fuse plugs, autobrakes, speed brakes, and thrust reversers.

While the need for *antiskid* braking systems was recognized due to higher takeoff and landing speeds in jet aircraft, most of the time antiskid features of brakes are not needed, as brakes are not applied hard enough to skid the tires. However, when the runway is wet and short, the antiskid system becomes very important to maximize braking effectiveness. Braking systems moved from the early antiskid systems for controlling tandem pairs of wheels in the four-wheel truck main gear configuration to controlling each wheel independently to modern digital antiskid systems that incorporate microprocessors to enhance the reliability and effectiveness. Low-melting-point *fuse plugs* in the wheels allow the tires to safely deflate during air pressure buildup when braking during high-speed rejected takeoffs instead of exploding and sending pieces of rubber flying into the airframe that occurred in earlier designs. The *automatic braking system* that enables automatic brake application on landing or during a rejected takeoff is a relatively recent feature to safety that frees the pilot to concentrate on other activities, such as applying reverse thrust and directional control of the airplane to achieve a smooth, safe stop on the runway. Another device used to enhance braking effectiveness is the *speed brake* (*wing spoiler*). These aerodynamic devices are located on the wings that serve to decrease lift and therefore increase download on the main wheels to enhance braking effectiveness. *Thrust reversers* are other devices that aid in safe stopping after touch down especially on short, slippery runways. Some designs are so effective that the airplane can stop within its required distance on a wet runway using only thrust reversers. The *stick shaker* is effective in avoiding aerodynamic stalls during both takeoff and landing. The stick shaker is a mechanical device that rapidly and noisily vibrates the control yoke of an aircraft to warn the pilot of an imminent stall and is mostly connected to the control column of jet aircraft.

Structural Safety

Through attention to detail design, manufacturing, maintenance, and inspection procedures commercial airplane designs have produced long-life, damage-tolerant structures with outstanding safety records.

The de Havilland DH 106 Comet was the world's first commercial jet airliner that had three catastrophic in-flight breakups within a year of entering airline service. One of the incidents' causative factors was dangerous concentrations of stress around some of the square windows. This led to the redesigning of windows to the current oval shape that exist on aircraft. Aircraft are designed to be damage-tolerant or fail-safe. This concept requires that a specified level of residual strength be maintained after complete failure or partial failure of a single principal structural element. A major issue facing the airlines currently is aging aircraft. By definition, an aging aircraft is one that is being operated near or beyond its originally projected design life of calendar years, flight cycles, or flight hours. The two important considerations of age are the number of flight cycles and the number of flight hours accumulated in service. Fatigue and corrosion are the primary concerns about aging aircraft. Fatigue damage to the fuselage is caused primarily by the repeated application of the pressure cycle that occurs during every flight. Fatigue damage to the wings is caused by the ground-air-ground cycle that occurs during every flight, pilot-induced maneuvers, and turbulence in the air. Thus, the goal of measuring aircraft structural safety by flight hours is more important for the wings than it is for the fuselage. With proper inspection, maintenance, and repair, the life of the aircraft structure could be unlimited.

Fire

Fire and its toxic smoke from burning aircraft materials have caused deaths. The Air Canada Flight 797 accident in 1983 had a significant impact on global aviation safety regulations, which were updated as a result of the accident. What evolved were new requirements to install smoke detectors in lavatories, strip lights marking paths to exit doors, and increased firefighting training and equipment for crew became standard across the industry. Evacuation requirements were also updated to mandate that aircraft manufacturers demonstrate that their aircraft could be evacuated within 90 seconds of the commencement of an evacuation with half the emergency exits blocked. According to studies, 90 seconds is the time needed to evacuate before there can be a large fire or explosions, or before fumes fill the cabin. Instructing passengers seated in over wing exits to assist in an emergency situation were also included as a requirement. Advanced materials for seat fabric and insulation have given between 40 and 60 additional seconds to people on board to evacuate before the cabin gets filled with fire and potential deadly fumes. In-flight fire in the cargo hold is also an issue hence cargo holds of most airliners are now equipped with automated halon fire extinguishing systems to fight fires that may occur in baggage holds.

Human Factors Issues on the Flight Deck

About 60%–80% of aviation accidents are attributed to human error. Human factors study and apply data on human capabilities and limitations to designing systems (equipment, tasks, environments, and the human–equipment interface) that are *safe and maximize human performance*. Understanding human factors is important to systems where humans interact with sophisticated equipment where human error can cause catastrophic accidents. The application of human factors is of particular importance on the flight deck where the human–machine interface often becomes a determining factor in the event of an emergency, where correct and timely decisions make the difference between life and death. Sample human factor applications on the flight deck include the comfort of the seats on the flight deck, the mental and physical preparedness of the pilots and copilots to fly, the visibility of the ramp area when looking through the windshield, the ability to blind-reach specific controls on the panels by touch alone, properly monitoring the flight instruments, the ease of interpreting and understanding audio and written information, the color-coding of annunciator lights on the display panel, ability to effectively communicate between pilots in the cockpit, ability of the flight crew to maintain situation awareness, ability to recognize and differentiate between runway and taxiway lighting against a backdrop of city lighting, and many others.

Technology improvements on flight decks have made significant contributions to improving safety in the areas of radio communication and inertial navigation, approach systems, and greatly simplified cockpit controls and displays. Some of these flight deck technology changes include crew alerting and monitoring systems, moving map displays, engine-indicating and crew-alerting system (EICAS), glass cockpit displays with color enhancement, ground-proximity warning system (GPWS), traffic collision avoidance system (TCAS), aircraft communications addressing and reporting system (ACARS), flight management system (FMS), heads-up display (HUD), and several other redundant and automated systems.

Pilot Fatigue

Fatigue is a physiological state of reduced mental or physical performance capability resulting from sleep loss or extended wakefulness, circadian phase, or workload. Fatigue is particularly prevalent among pilots because of unpredictable work hours, long duty periods, circadian disruption, and insufficient sleep. Fatigue significantly increases the chance of pilot error that can lead to accidents. While regulators attempt to mitigate fatigue by limiting the number of hours pilots are allowed to fly over varying periods of time, these restrictions may not always be sufficient.

Cabin Safety

Some of the initiatives that increase the likelihood of passenger survivability and effective evacuation in aviation accidents include:

- The NTSB recommended improvements in life preservers, passenger briefings, cabin safety data cards, emergency-evacuation slides, and floatation devices for infants, and crew postcrash survival training.
- Required protective breathing equipment for flight crews and cabin attendants, without which they could easily be overcome by fire and smoke and could not use fire extinguishers effectively.
- Fire-blocking seat cushions to prevent fire or to mitigate its effects. FAA Advisory Circular 120-80 (FAA, 2014) provides detailed guidance on how to deal with in-flight fires, emphasizing the importance of crewmembers taking immediate and aggressive action.
- Emergency floor lighting to improve the chances and speed of evacuation under conditions where there is significant smoke in the cabin.
- Stronger seats that must be able to withstand 16 times the force of gravity are required for Part 121 aircraft that were built after October 27, 2009. Seats must undergo dynamic testing with test dummies to ensure they are effective in a realistic aviation crash environment.
- Other improvements through the years include impact resistant seat frames, and airplane wings and engines designed to shear off to absorb impact forces.

Atmospheric Issues in Aviation

High-altitude flight can be significantly impacted by diverse atmospheric conditions, some of the more important ones being turbulence, wind shear, volcanic ash, ice, and precipitation.

Turbulence

Most injuries incurred due to turbulence are preventable if the passengers wear their seat belts. Studies have shown that during turbulence it was important not to change aircraft trim, but to disengage the early autopilot's auto trim feature and airspeed hold only if necessary, and to fly attitude and let the airspeed and altitude vary somewhat. Areas of concentration to address turbulence include turbulence forecasting, flight crew training, and crew procedures in areas where turbulence is anticipated. Detection and avoidance are the two main approaches addressing the turbulence issue. In this regard the FAA Aviation Weather Research program has a multidisciplinary team addressing the turbulence issue, and the National Center for Atmospheric Research (NCAR) is working on new algorithms for using data from the National Weather Service (NWS) Doppler weather radars to detect turbulence.

Wind Shear or Microburst

A wind shear is a change in wind speed and/or direction over a relatively short distance in the atmosphere. A microburst is a localized column of sinking air that drops down in a thunderstorm. Wind shear during takeoff and landing and winds-aloft hazard in mountain waves especially in high-risk areas such as the Rocky Mountains of the United States are two additional flying hazards to be contended with. Strategies to handle wind shear include training crews on avoidance of the phenomena, better detection of the conditions that can produce wind shear and alerting the crew, and getting maximum performance from the airplane (incorporating latest technologies in advanced flight decks) if the crew inadvertently encountered wind shear.

Volcanic Ash

Volcanic ash from active volcanoes is hard and abrasive, and can quickly cause significant wear to propellers and turbo compressor blades, scratch cockpit windows, contaminate the cabin, damage avionics and impair visibility. The ash can contaminate fuel and water systems, jam gears, and make engines fail. Its particles have low-melting point, so they melt in the engines' combustion chamber then the ceramic mass sticks to turbine blades, fuel nozzles, and combustors, which can lead to engines flaming out. The ICAO (2012) has set a maximum limit of 4 mg of silicate ash per cubic meter in the clouds associated with eruptions of volcanoes as the safe limit of ash concentration for ingestion by jet engines.

Ice and Snow

Ice and snow can negatively affect the airframe and engine in flight or the tire-ground contact on the runway. A small amount of icing can greatly impair the ability of a wing to develop adequate lift hence regulations prohibit ice, snow, or even frost on the wings or tail, prior to takeoff. An accumulation of ice during flight can be catastrophic as well. Prevention of in-flight ice buildup on wings and tails is done either by routing heated air from jet engines through the leading edges of the wing or by use of inflatable rubber deicing boots that expand to break off any accumulated ice. Skidding on the runway is also an issue that is addressed by prompt snow

removal and deicing from runways. Under the revised certification standards, new transport aircraft designs must incorporate methods to detect icing and to activate the airframe ice protection systems.

Airport Safety

An airport provides facilities for landing, takeoff, shelter, passengers, fuel storage and fueling, supplies, and repair of aircraft. Airport operations are complex and diverse, with hazards and their severity varying by the type of operation. Airport design and location can have a large impact on aviation safety, especially for some airports that were originally built for propeller planes and those that are in congested areas where it is difficult to meet newer safety standards. What follows are airport safety issues covering airport terminal buildings, hangars and maintenance shops, ramp operations, and specialized airport services that include aviation fuel handling, and deicing and anti-icing operations.

Airport Terminal Buildings

Inadequate layout and facility size leads to overcrowding, which can cause dangerous conditions during evacuation in an emergency (ex. fire or terrorism). Due consideration for safety should be given during the design, construction, and modification of the facilities which are covered by the design standards and requirements for building materials, fire protection, and building egress. Some of these standards/regulatory bodies include the National Fire Protection Association (NFPA), OSHA, EPA, and other local, state, and federal agencies. A summary of important safety considerations for airport terminal facilities follows.

Hangars and Maintenance Shops

Information on planning and design guidance for airport terminals is included in FAA Advisory Circular ([FAA, 2016](#)) for non-hub locations. Construction of hangars is covered by federal, state, and local building codes and many NFPA standards. Operational issues are mostly covered by OSHA and EPA requirements. Some of the safety issues include:

- Electrical—ex. aircraft docks should be permanently bonded, grounded, and secured to a permanent structure such as a hangar floor. Primary sources of electric power to hangars should be approved for the location according to the National Electrical Code, NFPA 70, and aircraft hangars, NFPA 409.
- Storing and handling of compressed gas, flammables, and hazardous and toxic substances (addressed under OSHA 29 CFR 1910 Subparts H and Z).
- Painting and stripping are hazardous activities that use toxic chemicals, and thus must be performed in well-ventilated areas (e.g., paint booths). In addition, painting and stripping generate toxic wastes that must be contained and either recycled or disposed of appropriately. Therefore, these operations are governed by both OSHA and EPA regulations.
- Material handling equipment such as overhead and gantry cranes that are used to move large aircraft sections are regulated under OSHA 29 CFR 1910.179. Slings, chains, and hoists used to move or lift smaller aircraft parts and sections (e.g., aircraft jacking) are regulated under OSHA 29 CFR 1910.184.
- The use of powered material handling equipment, such as fork trucks and hand trucks, and the use and maintenance of batteries used to power these and other equipment are regulated under OSHA 29 CFR 1910.178.
- Hoist units, such as those used to reach large aircraft tails, should comply with OSHA 29 CFR Part 1910 Subpart F, Powered Platforms, Man lifts, and Vehicle-Mounted Work Platforms.
- Welding, cutting, brazing, and other hot works that have the potential to start fires are regulated under OSHA 29 CFR Part 1910 Subpart Q.
- Noise evaluation and hearing protection for processes such as riveting, sand blasting, grinding, polishing, and other noisy operations are regulated under OSHA 29 CFR 1910.95.

Ramp Operations

The ramp area is generally designed for aircraft, not the vehicles that service and/or operate in the proximity of the aircraft. Most of the signs and markings are for aircraft. The ramp area sees a diverse collection of high-paced activities that involve aircraft, vehicles, and individuals working in close proximity to one another. Some of these activities include: aircraft ground handling that may include taxiing, towing, chocking, parking, or tie-down; aircraft refueling; aircraft servicing to include catering, cleaning, food service, etc.; and baggage and cargo handling. The earlier activities lead to several occupational hazards that include: cuts (from antennas, pitot tubes, static discharge wicks, etc.), slips and falls on the ground and from elevations, strains and sprains from baggage handling, exposure to hazardous materials (fuel), contact with moving parts (propellers) and bumps (undersurface of fuselage), electrical hazards (tools, motor, generators, etc.), biohazards from blood and other potentially infectious fluid exposures during cleaning, high-pressure air and other fluid exposures from pressurized systems, noise from engines and other equipment, injury from jet blast, and weather conditions (heat, cold, snow, ice, and rain) that can increase the risk of injury.

Aviation Fuel Handling

Fuel handling is an important safety issue to the fuelers and the operation of the aircraft. Failure to adhere to safe operating procedures when fueling aircraft and/or transporting fuel from one location to another on the airport can result in major disasters. Repeated contact with aviation fuels can cause skin irritation and dermatitis. Fuels contain additives such as benzene and can be toxic if inhaled or swallowed. Fuel contamination is a major safety issue as it can affect the operation of an aircraft. Contamination can occur by refueling an aircraft with contaminated fuel or the wrong fuel grade or type. Contaminants include rust, water, microbial growths, paint, metal, rubber, and lint. Explosions and fires during fueling or fuel transfer from sparks or static discharge are another safety hazards. Hazards from fuel spills and leaks from underground storage tanks present varying degrees of safety and environmental issues depending on the size of the spill and the kind of response required.

Deicing and Anti-Icing

Ice and snow on control, airfoil, and sensor surfaces can have serious consequences on the safe operation of the aircraft, so when freezing or near-freezing conditions exist, the aircraft should be sprayed with deicing fluid before takeoff. Hazards posed by this operation include damage to the aircraft by the deicing equipment, application of deicing fluid in areas where it should be avoided (static ports, pitot heads, angle-of-attack sensors, the engine, and other inlets), inhalation and ingestion hazards to the deicing crew, and hazards to the crew and passengers if the cabin air intakes are not shut off during deicing.

Foreign Object Debris

Foreign object debris (FOD) includes items left in the aircraft structure during manufacture, maintenance, or debris on the runway. Such items can damage engines and other parts of the aircraft. In July 2000, Air France Flight 4590 (a Concorde) ran over debris on the runway during takeoff, blowing a tire and puncturing a fuel tank. The subsequent fire and engine failure caused the aircraft to crash into a hotel after takeoff, killing all 109 people aboard and 4 more people in the hotel.

Bird Strike

Bird strikes have caused fatal accidents through engine failures following bird ingestion and breaking cockpit windshields. While jet engines are designed to withstand the ingestion of birds of a specified weight and number, ingesting birds beyond the “designed-for” limit can be catastrophic as witnessed by US Airways Flight 1549 which encountered a flock of Canada geese. In this case, pilot skill and luck led to all passengers surviving. The outcome of a bird strike depends on the number and weight of birds and where they strike the fan blade span or the nose cone. The highest risk of a bird strike occurs during takeoff and landing in the vicinity of airports, and during low-level flying. Airports use a variety of countermeasures including shotgun patrols, playing recorded sounds of predators through loudspeakers, or employing falcons, planting poisonous grass to detract birds and to insects that attract the birds, and avoiding conditions that attract birds to the area (e.g., landfills).

Runway Incursions

A runway incursion is a type of runway safety incident that involves an incorrect presence of a vehicle, person, animal, or another aircraft on the runway. The FAA classification of a runway incursion in order of increasing severity is:

- Category D—Incident that meets the definition of runway incursion such as incorrect presence of a single vehicle/person/aircraft on the protected area of a surface designated for the landing and takeoff of aircraft but with no immediate safety consequences.
- Category C—An incident characterized by ample time and/or distance to avoid a collision.
- Category B—An incident in which separation decreases and there is a significant potential for collision, which may result in a time critical corrective/evasive response to avoid a collision.
- Category A—A serious incident in which a collision was narrowly avoided.
- Accident—An incursion that resulted in a collision.

The worst aviation disaster on record was the result of two Boeing 747s colliding on a runway at Tenerife Airport in the Spanish Canary Islands in 1977. This is the most severe case of a runway incursion, one that resulted in an accident taking 583 lives. Incursions occur due to (Rodrigues, 2002):

- Operational errors: This is an action of an air traffic controller that results in a less than the recommended separation between two or more aircraft, or between an aircraft and obstacles (vehicles, equipment, personnel, etc.) on runways, or an aircraft landing or departing on a closed runway.
- Pilot deviation: This is a violation any federal aviation regulation, for example, failing to observe an ATC instruction not to cross an active runway when on an authorized route to a gate.
- Vehicle/pedestrian deviation: This is when vehicles, pedestrians, or other objects interfere with aircraft operations by entering a restricted area without authorization from air traffic control.

The airport ground operations environment is a complex system of markings, lighting, and signage with varying layouts by airport. In bad weather, visibility decreases that further increases the complexity of the environment. Night operations complicate issues additionally as airport lighting blend with background city lights. It is under these conditions that large numbers of individuals with varying levels of experience, training, and language proficiency must coordinate actions and procedures that are needed for smooth and safe operations while interfacing with large numbers of individuals, airplanes, and ground vehicles that are in close proximity to one another. It is therefore easy to understand why under these conditions, individuals are prone to error and incidents occur. Given the growth in air travel, things are going to get worse with the number of these events increasing over time. Additional information on runway incursion may be found in the reference section by [Rodrigues \(2004\)](#).

Managing Safety in Aviation

This section deals with how the aviation sector manages risk associated with the hazards outlined in the previous sections. Aviation safety management is a system in which risks associated with aviation undertakings, related directly or indirectly to support the operation of aircraft, are reduced and controlled to acceptable levels. Safety risks arise from undesired, unplanned, uncontrolled events (hazards outlined in the previous sections) that can cause adverse effects to personnel, equipment, environment, property, and reputation within a defined system. Risk is the combination of the probability of occurrence of the hazard and the severity of its effects, and is expressed as:

$$\text{RISK} = \text{Probability} \times \text{severity}$$

- Probability = Loss event/unit of time or activity
- Severity = Loss/loss event
- Risk = Expected loss/unit time or activity

Risk management is the overall process of identifying, evaluating, controlling, and accepting risks, while following all health, safety, and environmental regulations and best practices. Safety can be expressed as a level of risk associated with the operation of a system.

Safety management systems (SMS) is a term describing a standardized approach to controlling risk across an entire organization that promotes the sharing of safety data and best practices. In the United States, the SMS framework consists of 4 components or pillars and 12 elements within those components ([FAA, 2010](#)). The four components of SMS are:

- Safety policy—Establishes senior management's commitment to continually improve safety; defines the methods, processes, and organizational structure needed to meet safety goals.
- Safety risk management (SRM)—Determines the need for, and adequacy of, new or revised risk controls based on the assessment of acceptable risk.
- Safety assurance (SA)—Evaluates the continued effectiveness of implemented risk control strategies, and supports the identification of new hazards.
- Safety promotion—Includes training, communication, and other actions to create a positive safety culture within all levels of the workforce.

Conclusions

Present-day commercial aviation is a USHRI that manages to operate with a great degree of safety in a high-risk environment. In aviation, it is practically impossible to attain an environment devoid of threats to safety given that individuals interface with objects that move very fast under human control and have high potential energy. Safety is a top priority for airlines as it can affect profitability. Since efficiency is often a natural by-product of safety, a commercial aviation operator that manages safety risk adequately will often also gain in operational efficiencies. This article reviewed safety hazards that are encountered in the aviation transportation system and how the aviation sector manages risk associated with these hazards through an SMS.

ICAO9284 Technical Instructions for the Safe Transport of Dangerous Goods by Air
ULD Aircraft unit load device

Introduction

Aviation safety is the major priority for the transportation of passengers and air freight in the global airline industry. Air freight is anything that is transported in an aircraft except for mail or passenger luggage carried under a passenger ticket but including baggage shipped under the cover of an airwaybill (Hui et al., 2004). Air freight is carried by combination airlines in the lower decks of their passenger aircraft, dedicated all-cargo airlines, and by the integrators, for example, DHL Express, FedEx and United Parcel Service (UPS) (Baxter and Bardell, 2017; Dresner and Zou, 2017; Morrell and Kleing, 2019).

When transporting goods by any mode (air, sea, rail, truck), an item is considered hazardous if it is explosive, corrosive, flammable, toxic, or radioactive. Dangerous goods are articles or substances, which are capable of posing a risk to health, safety, property, or the environment and which are shown in the list of dangerous goods in the International Civil Aviation Organization (ICAO) Technical Instructions or which are classified according to those instructions (International Civil Aviation Organization, 2020b).

Figure 1 The annual growth in global air freight ton kilometers performed: 1945–18.

The transport of dangerous goods by air is subject to strict regulation at both the government and industry level. The aim of this article is to provide an overview of the carriage of dangerous goods by the air freight mode and the associated regulatory framework that is applicable to all actors participating in the global air freight industry.

Historical Trends in World Air Freight Growth

The world scheduled air transport industry commenced largely during the post-World War 1 period. Following the Berlin Air Lift, after the World War II, the world air freight industry began to form itself around the freight-carrying capabilities of commercial aircraft. Since those early times, the international air cargo mode has developed into a high growth industry ([Fig. 1](#)) ([Sales, 2013](#)).

Air freight was considered a sideline operation to postal and passenger traffic until 1941, when the United States “Big Four” domestic airlines [American, Eastern, Trans World Airlines (TWA), and United Airlines] formed Air Cargo Inc. to commence regular cargo flights. By the end of 1941, many of the US-based airlines, including TWA, had commenced their own independent air cargo services ([Chiavi, 2017](#)). Also, around this time Pan American World Airways an extensive airfreight operation.

Prior to the 1960s, airlines considered air freight as a way of filling spare aircraft hold capacity on what were principally narrow bodied passenger aircraft. The introduction of jet aircraft, particularly the Boeing B707 and the McDonnell Douglas DC-8 in the early 1960s, stimulated nearly 10 years of rapid air cargo growth, the annual growth rate averaged around 16% during this period ([Hayuth, 1983](#)).

During the 1970s, the annual world air freight growth averaged around 8.6%. The introduction of wide-body aircraft in the early 1970s, such as the McDonnell Douglas DC10, Lockheed L1011 Tristar, Airbus A300, and particularly the first all-freight aircraft, the Boeing B747 freighter aircraft in 1972, had a pronounced effect on the air cargo industry ([Wood et al., 2001](#)). These new wide-body aircraft enabled airlines to offer significantly greater air cargo capacity as they introduced the new aircraft type on more and more routes, while also increasing the size of air cargo consignments that could be carried. Around this time, scheduled airlines also took their air cargo services more seriously and introduced more flexible and competitive pricing in order to secure greater volumes of air cargo traffic ([United Kingdom Department of Transport, 2000](#)).

In the 1980s the world air freight growth rate averaged around 7.2% per annum. During the first half of the 1980s growth in world freight ton kilometers performed (FTKs) was stronger on scheduled passenger services. In the latter part of the 1980s dedicated freight services grew faster than on passenger services. There was a continued increase in the annual growth rate during the 1990s of 7.7% ([Doganis, 2010](#)). Since 1990 there have been variable growth levels on both scheduled passenger and dedicated freight services.

The growing importance of dedicated freighter services is due to customer demand for superior services and stricter safety regulations on lower hold cargo aboard passenger services ([Boeing Commercial Airplanes, 2006](#)). The imbalance in air cargo traffic flows is a further factor ([Kupfer et al., 2011](#)), according to Airbus. Most of the growth of world air cargo (as measured by FTKs) from 1980 to 2017 occurred in scheduled international traffic. Representing 70% in 1981, scheduled international services increased their share to around 87% in 2017 ([International Civil Aviation Organization, 2018](#)).

Probably the most significant development to occur in the world air cargo industry over the past 30 years has been the rapid growth and development of the air express sector. Express package services were pioneered by Federal Express (FedEx) in the United States in 1973 ([Doganis, 2010](#); [Smith, 2001](#)). FedEx identified a number of key product features hitherto unrecognized by the traditional air cargo industry: the requirement for door-to-door and overnight package transportation for urgent/time-important

Figure 2 The air cargo supply chain, illustrating the key players from shipper to consignee.

small parcels and documents. Instead of selling services purely on the basis of weight and price, customer convenience, rapid shipment times and reliability became the principal product features (United Kingdom Department of Transport, 2000). The company developed rapidly and earned \$USD 1 billion in annual revenue in 1983. In 2000 Federal Express was renamed FedEx (Smith, 2001). The integrators services are underpinned by the use of dedicated, efficient global multimodal networks—they own and operate most of their own aircraft, smaller planes, trucks, and automated handling and storage facilities (Milenkovic, 2001). The integrators introduced guaranteed delivery times with a pricing structure to match. Hence, the integrators supplement their air services with extensive ground transport to provide time-definite delivery to their customers with continuous shipment tracking and, if necessary, logistics expertise to support just-in-time (JIT) inventory control strategies. These firms also provide value added services, such as, customs brokerage and logistics services, warehousing, and inventory control (Cavusgil et al., 2012). **The Key Players in the Global Air Cargo Supply Chain**

Air cargo service providers are a heterogeneous group that provide a variety of logistics and supply chain services and expertise (Doganis, 2010; Reynolds-Feighan, 2001). The air cargo industry consists of various commercial organizations that provide shippers and/or consignees with air cargo services. Fig. 2 shows the relationship between the major actors in the world air cargo industry. The distinction amongst these actors is often clouded. Airlines offer small-package services and freight forwarders lease or operate aircraft dedicated to their requirements. There are many contracting and subcontracting operations in which a firm in one market segment of the industry works closely with a firm in another market segment (Wood et al., 2001). All sizes of aircraft are used (Morrell and Kleing, 2019; Wraight, 2017). Airlines often offer more than one level of service, meaning that the shipper has some choices as to how quickly the cargo consignment will move and for which additional services they are willing to pay (Wood et al., 2001).

Shippers

The shipper, also known as the consignor, because they consign or entrust their consignment to the actors undertaking the physical transfer process, may be a company or an individual, exporting either general or perishable goods (The International Air Cargo Association, 1998). The shipper, the owner of the goods, establishes the initial link in the air freight chain (Damsgaard, 1999). To ship their goods to a customer, a shipper will generally contact several freight forwarders to find cargo space and obtain the best price and service offered (Beifert, 2016; Morrell and Kleing, 2019; Sales, 2016).

Trucking Firms

Trucking companies provide road transport services for producer/shippers transporting their products from their premises to their assigned freight forwarder or to the airport where the consignments are handled and stored in preparation for their designated flight.

International Air Freight Forwarders

The process of moving air cargo is more complex than for passenger traffic. For example, it involves packaging, extensive and complex documentation, insurance, pick-up and/or collection, and customs clearance. This complexity has encouraged the growth of specialist firms, the freight forwarders (Dempsey and Gesell, 1997). International air freight forwarders can be defined as ‘international trade specialists who provides a variety of functions and services to facilitate the movement of cross-border shipments’ (Murphy and Daley, 1996, p. 5). International air freight forwarders provide the full link between shippers and consignees, from surface point to surface point and also act as the interface between the shipper and the airline (Dempsey and Gesell, 1997; Ohashi et al., 2005).

International air freight forwarders contract with airlines for the physical carriage of goods, purchase block cargo space on their flights, consolidate cargo consignments from multiple shippers, and operate—or contract with—complementary surface transportation service providers (Al-Hajri, 1999). Due to economies of scale, international air freight forwarders are able to offer “consolidation” services that are often cheaper than those which the exporter could negotiate directly with the transportation provider (Corley, 2002). The freight forwarder makes a profit by consolidating shipments and obtaining a quantity or volume discount from the airline for the larger shipment size (Dempsey and Gesell, 1997; Wood et al., 2001).

Other services provided by air freight forwarders on behalf of shippers include customs brokerage, transport insurance, warehousing and distribution, loading airline air cargo containers (ULDs), documentation, (Bruins, 2006), banking requirements, trucking (pick-up or delivery), cargo space reservations for shippers, documentation preparation, and in some instances, shipment packing and cargo insurance. Air freight forwarders may also manage, under contract, some of the downstream production functions of a supply chain, offering services in warehousing, quality control, inventory control, and JIT delivery operations of firms, often large multinationals (Wan et al., 1998).

General Sales Agents

The general sales agent (GSA) is an appointed representative of the airline and can be viewed as the airline’s outsourcing partner (Hosie et al., 2012; Sales, 2016). GSAs serve as an intermediary between their client airlines and freight forwarders. GSAs handle their client airlines sales, marketing, and operational activities in the specified territory. Other functions that may be performed by GSAs include traffic handling, maintenance, catering, flight dispatch, customer service, and warehousing. GSAs typically directly market their client airlines services to the freight forwarders (Hosie et al., 2012).

Airports

Normally airports act as landlords and infrastructure providers charging landing fees and aircraft apron parking fees to airlines (their primary customers) and charging rent to other air cargo related service providers, for example, cargo terminal operators (CTOs) (Ryan, 2008; United Kingdom Department of Transport, 2000).

Cargo Terminal Operators

Cargo handling at an airport is typically performed by an airline’s own staff or is outsourced to dedicated third-party service providers or other airlines. CTOs provide the handling facilities necessary to accept air cargo consignments from international air freight forwarders and shippers, check shipment weights, and prepare aircraft load plans (Morrell and Kleing, 2019). They also store the consignment until it has been cleared for export by the customs authority or held for at least 24 hours at the terminal for safety reasons (Damsgaard, 1999). The CTO then arranges for the consignment to be loaded on the designated aircraft (Caves, 2015). At the destination, an air CTO accepts cargo from incoming flights and stores the cargo until it has been cleared and released by the receiving country’s customs authority. A freight forwarder then typically thereafter collects the consignment and arranges delivery to the consignee (Wan et al., 1998).

National Customs Authority

National Customs authorities perform two basic functions: trade facilitation and customs control (Zhang et al., 2017). Customs controls includes intellectual property rights protection, the prevention of the infiltration of prohibited imports, such as illicit drugs or other dangerous substances, and also tariff collection (Zhang, 2003). Customs authorities normally receive an application for export approval from a shipper or a freight forwarder on his behalf. After checking the application customs issues an export clearance authority. Similarly, at the receiving country, customs receive an application for import clearance and, when issued, the CTO may release the consignment into the custody of a freight forwarder (Damsgaard, 1999).

Ramp Handling Agent

When aircraft are on the ground in between flights, they require various ground handling services to be performed, for example, aircraft loading/unloading, cargo handling, lavatory services, aircraft towing, or pushback (Kazda and Caves, 2015; Wu, 2010; Thompson, 2007; Damsgaard, 1999). Operator personnel collect the freight from the CTO operator and are responsible for loading the cargo on to the correct aircraft. At the destination, they unload the aircraft and deliver the incoming consignments to the airline’s contracted CTO’s terminal.

Airlines

An airline provides transportation for air cargo consignments from the airport of origin to the destination airport (Roebuck, 2013). In the global air cargo industry there are three principal types of air cargo-carrying airlines: combination passenger airlines, dedicated all-cargo airlines, and the integrators. Combination airlines include airlines that provide both passenger and air cargo services,

transporting air cargo in the lower deck belly holds of their passenger aircraft (Dresner and Zou, 2017; Morrell and Kleing, 2019). Most international carriers fall into this category. Combination airlines typically only offer airport-to-airport services and rely on air freight forwarders to perform the remaining transport logistics. Dedicated all-cargo airlines, such as Japan's Nippon Cargo Airlines, operate dedicated scheduled freighter flights on routes where there is regular heavy air cargo demand or where the potential passenger traffic is not large. These airlines typically carry air cargo only on an airport-to-airport basis and emphasize long-haul services (Dresner and Zou, 2017). The integrators are firms that integrate the air and ground transport services traditionally performed by separate firms, for example, airlines, and freight forwarders, to provide a full door-to-door service (Merkert and Alexander, 2018). Most international carriers fall into this category. Combination airlines typically only offer airport-to-airport services and rely on air freight forwarders to perform the remaining transport logistics (Wensveen, 2016). Dedicated all-cargo service (Leinbach and Bowen, 2007). Furthermore, the integrators' business model not only focuses on the provision of a fully integrated door-to-door product offering but also on the provision of supply chain and logistics solutions, which are underpinned by highly advanced IT systems. The largest integrators are FedEx, UPS, and DHL Express. Charter airlines either operate ad hoc services when there is a special requirement, fly to unusual destinations not served by other types of airline or operate scheduled services on behalf of specific clients. The cargo space of the entire or part of the aircraft can be chartered (Roebuck, 2013; Sales, 2016).

Most air cargo is carried in containers or ULDs, with the remainder transported loose in dedicated aircraft lower deck belly-hold compartments (Morrell and Kleing, 2019). On wide-body flights the consignments are loaded into special airline containers (ULDs) normally made of aluminum or on pallets (Ashford et al., 2013; Damsgaard, 1999).

Consignees

The importer or consignee is the receiver of the goods. An importer may be a company or an individual. The importer is normally responsible for the destination processes, such as, customs clearance and product distribution (The International Air Cargo Association, 1998).

The Provision of Air Cargo Capacity

Combination Aircraft Belly-Hold Air Cargo Capacity

As a by-product of aeronautical design, space is created below the main passenger deck of aircraft where passenger's luggage, cargo, and mail can be carried. When passengers are carried on the aircraft main deck, and cargo is carried below in the lower deck "belly hold" compartments, it is described as combination aircraft (Dempsey and Gesell, 1997). Importantly, the design of passenger aircraft is dictated by passenger requirements, space for air cargo is simply what is left over in the otherwise unusable space below the main passenger deck of the aircraft that is not required for the stowage of passengers luggage and that exists simply due to the aerodynamic requirements for a tubular shape for the aircraft fuselage. Air cargo is also a by-product in the sense that it is normally carried by combination airlines to where passengers want to travel, which is not necessarily where the air cargo wants to go. Combination carriers' networks are predicated on where passengers desire to travel to. Some combination airlines that operate dedicated freighter services tend to operate these aircraft to the same airports as their passenger services due to operational and cost synergies (Tretheway and Andriulaitis, 2010).

Combination airlines air cargo capacity may come in the form of narrow bodied, single-aisle aircraft, such as, the Airbus A320 aircraft, or wide-bodied, twin aisle aircraft, such as the Airbus A330-300 aircraft. Other wide-bodied aircraft include the Boeing B787, 777, and 747 aircraft as well as the Airbus A380 aircraft.

Combination airlines cargo operations are principally long haul, with large volumes of cargo being transshipped onto shorter-haul feeder services. The high utilization of long-haul passenger aircraft often justifies the purchase (or lease) of new aircraft for these services by the combination airlines (Button and Slough, 2000).

Freighter Aircraft Air Cargo Hold Capacity

By removing all of the unnecessary passenger-related facilities, thereby saving weight, a Boeing B747-400 freighter can carry a cargo payload of 113 tons (Boeing Commercial Airplanes, 2010); the same aircraft with a main passenger deck and lower deck belly-hold cargo has a typical payload of approximately 60–70 tons. The world's freighter fleet is divided into three freighter aircraft size categories: small capacity/standard body freighters, medium size freighters, and large wide-body sized freighter aircraft (Dahl, 2009; Morrell and Kleing, 2019).

Safe Transportation of Dangerous Goods by Air

Dangerous goods are defined as any articles or substances which are capable of posing a risk to health, safety, property or the environment and which are shown in the list of dangerous goods as published in the Technical Instructions or which are classified according to those Instructions (International Civil Aviation Organization, 2020c). The provisions of Annex 18 (A18) to the 1944 Chicago Convention on International Civil Aviation govern the international transport of dangerous goods by the air freight mode (International Civil Aviation Organization, 2020a). The broad provisions of A18 are amplified by the detailed specifications of the Technical Instructions for the Safe Transport of Dangerous Goods by Air (ICAO Document 9284) (International Civil Aviation

Organization, 2020d). That is, the legal provisions are set down in A18, while the technical guidance is given in ICAO9284 (Abeyratne, 2012). In general, the transportation of dangerous goods by air is forbidden, unless it is done so in accordance with ICAO9284. The definition of dangerous goods is specified in ICAO9284 (Blumenkron, 2017). Further to this, certain goods are identified as forbidden, which can be carried under certain exceptions (e.g., infected live animals), while others can be forbidden under any circumstance (explosives) (International Civil Aviation Organization, 2011a).

Dangerous goods must be packed as stipulated in A18 and ICAO9284. Packaging used for the transport of dangerous goods as air cargo must be of good quality, well constructed, and closed securely to prevent leakage. The packaging must also be appropriate for the contents; such that they are resistant to any chemical reaction or other detrimental effect of the contents. Material and construction specifications, and testing requirements are also laid out in ICAO9284 for the packaging. Inner packaging must be used to secure and/or cushion the contents to prevent any breakage, leakage, or to control their movement within the outer packaging. Packaging cannot be reused until it has been inspected and found free from corrosion or other damage. If packaging is reused, measures must be taken to prevent contamination of subsequent contents. Also, no harmful amount of a dangerous substance should adhere to the outside of packages (International Civil Aviation Organization, 2011a, p. 23).

Packages of dangerous goods being sent by air must be labeled with appropriate labels and in accordance with the provisions set forth in ICAO9284. These packages are required to be marked with the proper shipping name of its contents and, when assigned, the appropriate UN number and such other markings as may be specified in ICAO9284. Packages manufactured to specification contained in ICAO9284 must be marked in accordance with those provisions (International Civil Aviation Organization, 2011a). To that end, packages that do not meet the appropriate packaging specification contained in ICAO9284 cannot be marked as if they do.

Prior to someone offering a package or overpack (a container with one or more packages) of dangerous goods for transport by air, they must ensure that the dangerous goods are not forbidden for transport by air and are properly classified, packed, marked, labeled, and accompanied by a properly executed dangerous goods transport document, as specified in A18 and ICAO9284. The individual who offers dangerous goods for transport by air must complete, sign, and provide a dangerous goods transport document to the operator, which must contain the information required by ICAO9284. This transport document must include a declaration signed by the individual who offered the dangerous goods for transport by air. This declaration must indicate that the dangerous goods are fully and accurately described by their proper shipping names and that they are classified, packed, marked, labeled, and in proper condition for transport by air in accordance with ICAO9284 (International Civil Aviation Organization, 2011a).

The carriage of dangerous goods by air is included in the scope of the operator's safety management system (Annex 19 to the 1944 *Convention on International Civil Aviation*). Operators also need to comply with the responsibilities outlined in A18. An operator must not accept dangerous goods for transport by air unless:

1. the dangerous goods are accompanied by a completed dangerous goods transport document (the exception being where ICAO9284 indicate that it is not required); and
2. the package containing the dangerous goods has been inspected in accordance with the acceptance procedures contained in ICAO9284 (Abeyratne, 2012; International Civil Aviation Organization, 2011a, p. 29).

Furthermore, an operator is required to develop and use an acceptance checklist to aid compliance with the provisions of A18 Chapter 8.1. Packages and overpacks containing dangerous goods and aircraft unit load devices (ULDs) containing radioactive materials must be loaded and stowed on an aircraft in accordance with ICAO9284. Packages, overpacks, and ULDs containing dangerous goods (including radioactive materials) must be inspected for evidence of leakage or damage prior to being loaded on an aircraft. Leaking or damaged packages, overpacks, or ULDs must not be loaded on an aircraft. In the case where any package containing dangerous goods on an aircraft appears to be damaged or leaking, the operator must remove this from the aircraft, or arrange for its removal by an appropriate authority or organization (for hazardous substances for example). Following this, the operator must ensure that "similar" packages are in proper condition for transport by air and have not been contaminated. After the flight, these packages, overpacks, and ULDs must be reinspected for signs of damage or leakage while being unloaded. If damage or leakage is discovered, the area where the goods were stowed on the aircraft must also be inspected for damage or contamination (International Civil Aviation Organization, 2011a).

Packages containing dangerous goods, which might react dangerously with one another, should not be stowed either next to each other or in a position that would permit them to interact in the event of leakage. Packages containing toxic and infectious substances must be stowed on an aircraft in accordance with ICAO9284. Packages comprising radioactive materials must be stowed on an aircraft so that they are separated from persons, live animals, as well as undeveloped film, in accordance with ICAO9284. When dangerous goods are loaded in an aircraft, the operator must protect the dangerous goods from being damaged. The operator must also secure such goods in the aircraft in such a manner that will prevent any movement in flight which would change the orientation of the packages. In addition, packages of dangerous goods bearing the "cargo aircraft only" label shall be loaded in accordance with ICAO9284 (International Civil Aviation Organization, 2011a, p. 30).

The International Air Transport Association (IATA), the world's peak airline body, works closely with ICAO and local governments in the development of regulations for the carriage of dangerous goods by air (International Air Transport Association, 2020a). The IATA Dangerous Goods Regulations (DGR) is the worldwide reference for shipping dangerous goods via air and is the only standard recognized by airlines. The IATA DGR is a "field manual" version of the ICAO9284. The DGR draws from the industry's most trustworthy air cargo sources to help shippers classify, pack, mark, label, and document shipments of dangerous goods. In

addition, the DGR includes international dangerous goods air regulations, as well as state and airline requirements ([International Air Transport Association, 2020b](#)).

In the United States, the Federal Aviation Administration Hazardous Materials Regulations (HMR) prescribe the minimum requirements for the safe transportation of dangerous goods by air. These regulations describe how dangerous goods are classified, communicated, handled, and stowed. The HMR is published in Subchapter C of Title 49 of the Code of Federal Regulations (49 CFR, parts 171-180). The US Department of Transportation “Pipeline and Hazardous Materials Safety Administration” is responsible for the HMR ([United States Federal Aviation Administration, 2018](#)).

Substantive Safety

Overview of Historical Air Cargo Safety Occurrences

The ASN, a service of Flight Safety Foundation, includes within its accident database a total of 222 unique safety occurrences identified as air cargo occurrences, dating from 1941 to 2018. These are then further divided into five broad occurrence types which are issues commonly associated with air cargo occurrences; specifically, overloaded aircraft, wrong center of gravity, load shift in flight, fire or smoke (from the cargo consignments), and a leak (again of the cargo consignments) ([Aviation Safety Network, 2020b](#)). [Fig. 3A](#) shows the breakdown of these occurrence types. The dominant issue for air cargo accidents is clearly overloading the aircraft, which accounts for 53% of all the occurrences.

Broadly speaking, aviation safety occurrences can either result in fatalities or not ([Hoel et al., 2008](#)). According to ICAO, the percentage of official accidents in the last decade that has resulted in fatalities was 14%. From [Fig. 3B](#), 59% of air cargo related accidents were fatal. This means that accidents that are the result of issues associated with air cargo are more than four times more likely to result in fatalities. Similarly, we can also look at the outcome of accidents for the airframe. That is, while fatality is the metric used for people onboard the aircraft, the severity of an accident will also affect the aircraft as well, in terms of the level of damage. [Fig. 3C](#) shows that the outcome for the aircraft involved in air cargo occurrences is also significant, with only 5% of aircraft in air cargo related accidents being able to be repaired.

Another important characteristic of a safety occurrence to consider is in which phase of flight it happened. Typically, accident rates see a small spike at take-off (and initial climb out) and a significant spike at landing (and final approach), referred to as the critical phases of flight. That is, the risk of an accident is moderate (before flight), then high during take-off, then lower during cruise, and the high again for final approach and landing. But as seen in [Fig. 3D](#), for air cargo occurrences the risk of occurrences starts high during take-off, remains high through the climb, and is again high during the flight, and reduced for approach and landing. While the difference is interesting, it is not surprising. The nature of the accidents being the result of issues with the cargo means probabilistically the occurrence should happen earlier during the flight (the wrong CoG would manifest itself at take-off, etc.), and also during the longest time interval which corresponds to cruise (where issues such as fire associated with the cargo consignment).

The previous four characteristics are specifically detailed by ASN in the summary data of the accidents in the database. Further to this, the accident descriptions provided by ASN were coded qualitatively, to identify the EASA safety issues, as well as the ICAO occurrence category. First, the safety issue is used by EASA to assess the contributing factors in an occurrence. These are grouped into human factors (HFs), organizational (Org), equipment problems (EP), or environmental (E), which each in turn having more subcategories. Typically, HFs are associated with 80% of all aviation accidents ([Ferguson and Nelson, 2014](#)). We note here in [Fig. 3E](#) that in air cargo occurrences HFs contributes to 95% of all occurrences. Second, according to ICAO (2011b), occurrence categories are used to classify safety occurrences broadly to enable data analysis in an effort to the support of safety initiatives. There are 34 occurrence categories. As shown in [Fig. 3F](#) the most apparent of these is the RAMP category, which is used to classify occurrences that are the result of activities on the ramp in and around the aircraft. Noting that multiple categories apply to a single occurrence, RAMP was applicable to almost 89% of occurrences. The most common “outcome” for air cargo occurrences was loss of control in flight (LOCI), which occurred in 58% of occurrences, followed by runway excursions (RE) which occurred in 13% of occurrences. In continuing order of significance the other occurrence categories associated with air cargo occurrences are fire post impact (F-POST), fire nonimpact (F-NI), controlled flight into terrain (CFIT), system component failure – powerplant (SCF-PP), collision during take-off and landing (CTOL) with an obstacle, abnormal runway contact (ARC), and icing (ICE).

Rates of Air Cargo Accidents

[Fig. 4](#) shows the rates of accidents per million departures for major US carriers. The average for the six passenger airlines is approximately 1 accident per million departures. The rate for UPS and FedEx is below this, and they are the two largest air cargo operators in the United States. Looking at Atlas Air, a small and growing air cargo operator, it has an accident rate in excess of 4 times the average for passenger airlines. As such, we cannot say that air cargo operations are less safe than passenger operations, but there is clearly a distinction that needs to be made based on the size of the organization, and then the safety culture within that organization. In this example, it is important to note that Atlas Air is being compared to airlines which are much larger. It is a well-known fact that on average the smaller an operator is, the greater the risk involved with that operation. The key example of this is that fact that accident rates are much higher in general aviation compared to regular passenger transport ([Li, 2010](#)). If we continue and include additional small US air cargo operators (from largest to smallest), Kalitta Air has an accident rate of 4.6, Lynden Air Cargo Airlines has an accident rate of 8.3, and finally Centurion Air Cargo has an accident rate of 41 per million departures. The final point here is if

Figure 3 Pie charts showing the breakdown of cargo accidents by (A) occurrence types, (B) fatalness, (C) aircraft damage, (D) phase of flight, (E) EASA safety issue, and (F) ICAO occurrence category. Source: Adapted from [Aviation Safety Network \(2020a\)](#).

the data set is divided chronologically in half (Jan 2008 to Jun 2013, and Jul 2013 to Dec 2018), there is a dramatic improvement in accident rates over time. Specifically, for FedEx with four accidents, three occurred from 2008 to 2012, while one occurred in 2015. For UPS, two occurred from 2008 to 2012, while one occurred in the second half of 2013. Finally, for Atlas, two occurred from 2008 to 2012, and one occurred in 2018. During the same time period, the number of departures for each airline also increased, further reducing the accident rates.

Case Examples

Potentially the most infamous example of an air cargo safety occurrence is the tragic accident of National Airlines Flight 102 ([Bibel and Hedges, 2018](#)). This fatal accident was the result of human error in the securing of the cargo, which shifted during take-off, changing the aircraft center of gravity, in addition to physically damaging the aircraft controls needed to counteract the change in

Figure 4 ICAO Official accident rates per million revenue departures for major US carriers, from 2008 to 2018 (inclusive). Accident count from ICAO (2020a). Departure data from the [US Bureau of Transportation Statistics \(2020\)](#), including all domestic and international departure to and from the United States.

stability. While not the typical example outlined above (this would be an overload case), National Airlines 102 still exemplifies the common characteristics identified earlier; they are dominated by HFs, begin at the ramp, tend to result in LOCI, occur early in the flight (take-off here), and end fatally for the crew onboard with a destroyed aircraft.

According to [Kharoufah et al. \(2018\)](#), a classic case of poor HFs resulting in an accident would involve a Russian Aircraft operated in Africa. Victoria Air 3C-LLA is an example of this from 2001. This is a typical overload example, occurring during cruise. Again, the ramp category applies as the aircraft was overloaded in contradiction to proper weight and balance requirements for the aircraft, this time with a system component failure powerplant resulting again in a loss of control inflight. The accident is fatal with the aircraft damaged beyond repair ([Aviation Safety Network, 2020b](#)).

Conclusion

Dedicated air freight operations commenced in 1941, building on the passenger and postal operations. The industry grew rapidly since the 1960s, going from less than 3 billion FTKs to over 200 billion FTKs since 2016. The evolution of aircraft used in air transport has helped facilitate the growth of that air freight market, which in turn resulted in the development of dedicated all freight aircraft and airlines, in 1972 and 1973, respectively.

There is a significant and diverse number of “links” in the global air cargo supply chain. The most obvious of these are the shipper or consignor and the receiver or consignee. Currently the transport of goods by air is not done from door to door, so road transport services will be involved, typically facilitated by trucking firms. To avoid a consignor (or consignee) needing to engage with multiple entities for a “package” to be delivered from door to door, a specialist freight forwarder is typically utilized. As airlines have a vested interest in carrying goods, they have GSAs to capture business. An airport is an essential part of the supply chain, and at the airport dedicated air cargo terminals can exist for the express purpose of handling freight. These terminals will typically have national customs authorities integrated within them to ensure all goods in and out clear customs. The interface between the terminal and the aircraft is facilitated by ramp handling agents. The aircraft itself is operated by an airline, either a dedicated cargo airline, or combination airline providing both passenger and air cargo services.

The regulatory requirements for the international transport of dangerous goods by the air freight mode are given in the provisions of A18 to the 1944 *Chicago Convention on International Civil Aviation*. These broad provisions are supported by the detailed specifications of the Technical Instructions for the *Safe Transport of Dangerous Goods by Air* (ICAO Document 9284). These documents are essential to guarantee the safe transport of dangerous goods by air, and to ensure safety in general in the aviation industry when air cargo is involved.

Introduction

A conventional way for bicyclists—in this chapter referred to as cyclists—to avoid having collisions has been to equip the cycle with good brakes. When riding at low speeds, a rear brake may be enough. At higher speeds, to reduce braking distance, both wheels should have brakes. Also, locking up the front wheel can lead to loss of balance and crashing so antilock brakes are desirable but typically not provided. However, rim brakes typically do not lock the wheel unless very hard pressure is applied. In order not to get hit, the cycle or cyclist also needs to be seen, meaning good reflectors and illumination is important, the latter also helps the operator to see imperfections in the pavement. A cyclist should also have a bell or some other means to get the attention of other cyclists and pedestrians, and ideally of motorists as well.

Other characteristics that are important for cycling safety is that the rider is comfortable, can reach the ground without having to stretch or jump off the seat and that the rider has an upright position so they can see the roadway ahead. These are characteristics that also apply to cycling away from closed off roads. Racing cyclists obviously do not sit upright but they also should not be mixed with regular traffic. Finally, the most important characteristic may be to keep speeds low. Riding at speeds above 30 km/h can easily lead to serious injuries, if there is an incident. In the European Union (EU), electric cycles have a maximum allowed speed of 25 km/h for motor assistance and most of them have a hybrid system that maximizes the speed to roughly that downhill as well. Conventional pedal cycles do not have speed maximizers and that can create hazardous situations.

According to a survey with senior cyclists in Sweden (Leden, 2008; Leden et al., 2008), the most commonly used safety equipment is lights, which are, or at least “were” at the time of the survey, used by 81% of the respondents. Most common are battery-powered lights followed by traditional dynamo-operated ones where the generator touches the tire. Some respondents have a dynamo in the hub. The second most common equipment is a helmet, which is used by 80% of the elderly. The remaining fifth does not own one. About two-thirds of the respondents use a bicycle-bag or basket, and the same share have reflectors mounted on the bicycle. However, reflective vests are used only by 17% of the respondents, though in rural areas the usage is close to 50%. Rear-view mirrors are used by a few respondents only, but are desired by quite many respondents (28%). Winter tires and winter cycles are desired by one-fifth of the respondents. However, more than half of the respondents stated that they do not miss any equipment or that they have no opinion.

This chapter is not looking at the above outlined conventional safety equipment but is looking ahead at what bicycle collision avoidance systems should be implemented within the next few years, or over a slightly longer time frame.

Methodology

The content here is based on literature surveys, analysis of in-depth crash data, road user questionnaires, and questionnaires with experts on Intelligent Transportation Systems (ITS) and the usage of such systems for satisfying functional needs. Mostly European users and experts were included. Surveys and interviews with children and elderly are limited to Sweden. Assessments included the potential for avoiding collisions with a focus on children and elderly as cyclists and as pedestrians, so called Vulnerable Road Users (VRUs). Children and elderly as pedestrians are included here to get a full overview of the shortcoming and needs of these groups.

For decades, the main societal rule has been to more or less neglect the needs of the VRU groups. The PhD dissertation of the author (Leden, 1989), about the safety of cycling children and the effect of the street environment was quite an exception at the time. The theme continued with the author as supervisor of a dissertation about children as pedestrians and bicyclists (Johansson, 2004).

The theses focused on making the traffic environment more manageable and understandable for children satisfying the functional needs of children. The topic was further elaborated on within the Pedestrians' Quality Needs (PQN) network of The European COST 358 Project (Leden et al., 2014), the framework of a Fulbright project, in the EU project HUMANIST (Leden, 2008), and finally in the context of EU projects like Vulnerable Road Users and ITS, VRUITS. Participation in the EU Humanist project in 2007 and 2008 had as a goal to achieve a competence concerning vulnerable road users and ITS, leading to research on needs of senior (older) cyclists. This started with exploring Finnish in-depth crash data (VALT) and testing a set of hypotheses to find out reasons behind the higher risks for senior cyclists compared to other age groups. This was then used as a background for developing bicycle collision avoidance systems targeted to aid senior cyclists.

In the HUMANIST project, exploration behind the higher risks for senior cyclists included a survey of more than 500 elderly (65 years or older) members of the Swedish Cycling Promotion organization Cykelfrämjandet, and an expert questionnaire was distributed during the Velo-city 2007 conference to get experts' views on ITS-measure actions to be taken to satisfy the requests of senior cyclists. Altogether, 14 experts participated in these in-depth interviews (Leden, 2008).

Multiple-Comfort Model

There are a lot of models that can be used to explore the safety situation in more detail. One is the *Multiple-comfort model* proposed by the Finnish researcher Summala (2005) and modified below to fit exploration of the safety of cyclists (Silla et al., 2017). According to the model, the following five issues are the most important ones for explaining road user behavior on a strategic, tactical, and operational (individual) level: Safety margins (to survive), good or expected progress of trips, rule following (according to the law and social rules), vehicle/road system (bicycle and infrastructure), and pleasure of driving and pleasure of cycling.

Safety margins: Safety margins imply a concept of available time. It is, for example, important to make cyclists and cars visible to each other, for instance through warning lights, signs or messages in the infrastructure or in-vehicle alarms to warn them about conflicting road users. Otherwise, especially in darkness, safety margins tend to be insufficient. In critical situations, combined pedestrian/bicycle detection systems and emergency braking could be needed.

Good or expected progress of trips: Good or expected progress of trips is an important issue for cyclists. Cyclists like to maintain their speed and may hesitate when it comes to braking. Therefore, there should be detectors well in advance of signalized intersections to give cyclists the possibility to get a green light without having to slow down or dismount their bicycles. And, gradients, especially downhill, are hazardous for cyclists as especially cyclists are reluctant to brake.

Rule following: The analysis of Finnish in-depth crash data which focused on fatalities revealed that 80% of the cyclists had not obeyed some rule. Though this figure is certainly biased due to the fact that the conclusions are often based on the surviving car drivers' statements, rule following is obviously critical also to cyclists. Laws and regulations should enhance and secure communication between road users. Harmonization of rules within countries such as in the United States as well as between nearby countries, such as within the EU, is an important issue. For example in Southern and Eastern Europe there is a ban on phone use when cycling; whereas in Northern Europe there is no ban, except in Denmark.

Vehicle/road system (bicycle and infrastructure): According to Summala, the vehicle/road system is designed, so that cars usually have smooth car/road performance. This is often not the case for the cycle/road system. A cycle design, for example, elderly cyclists based on new technology is lacking. One of many issues could be to implement a bicycle-to-car communication system to facilitate communication between road users. Furthermore, adequate bicycle infrastructure is often missing, even in Europe—except in the Netherlands and Denmark—and if it exists, it often does not comply with the best practice. To achieve best practice, the management and political framework is crucial. An example of a “success story” from Helsinki in Finland is shown in the Video 1. Low motor-vehicle speed achieved by Intelligent Speed Adaptation (ISA) or by other means is a prerequisite for safety. This issue will be elaborated further in the section Multiple-need model. ITS could be a way to improve the safety of cyclists for example at intersections through early detection and prioritizing of vulnerable road users. Other means to increase safety include warning signals or warning lights to warn cyclists of approaching motor vehicles or vice versa at intersections. Such warning devices could also be useful when a motor vehicle is approaching a cyclist from behind (or a cyclist is approaching a pedestrian, but then the sound has to be “gentle” so that pedestrians are not scared). ITS can be used to get better guidance for and visibility of bicyclists at nighttime, for example through LED-lights in the pavements or by increasing the intensity of street lighting at times when cycle traffic is present.

Pleasure of cycling: The pleasure of cycling is an important topic especially for senior cyclists as 84% of the respondents in the survey of the HUMANIST project stated that the joy of riding is a reason for them to cycle. Measures should keep or increase the pleasure of cycling, and the amount of cycling. Examples are green waves at coordinated signals for cyclists, information on vacancy on bicycle racks and intelligent bikes.

According to the elderly, the biggest safety problems are potholes, slipperiness, and bad snow removal; 76%, 74%, and 70% of the respondents have referred to these factors as safety problems. Other major problems are curbstones and cars going too fast.

What the elderly say would increase their cycling is linked to what they say is important for increased traffic safety. Increased safety would lead to increased cycling among the elderly. Requests dealing with the physical design of roads are especially a demand for more and better cycle tracks and cycle paths. Communication between road users expressed as more and better consideration are also perceived to increase their feeling of safety and thereby increase their cycling.

Overall, it is important to note that an increase in cycling (e.g., due to the use of ITS) could lead to more fatalities and injuries for cyclists if adequate countermeasures are not taken. However, the risk per cyclists decreases even in a given environment when we have more people riding bicycles. Often, when improving a city cycle system, there is a possibility to choose between conventional and ITS countermeasures.

Multiple-Need Model

The *Multiple-need model* was developed to explore the safety of cyclists from the perspective of satisfying needs. According to the model, the following four issues are the most important ones to explain road user behavior on a strategic, tactical, and operational (individual) level: Environmental adaptation (in this context with focus on ITS issues), confidence and security enhancements, guidance (leading or navigating) and getting contact with and/or being localized.

Environmental Adaptation with Focus on ITS Issues

Environmental adaptation with focus on ITS issues implies a change of driver behavior to the limitations of VRUs, especially for children and elderly, by informing and/or alerting the driver or the VRU of a danger. However, especially regarding children, the question has been raised, if the traffic environment ought to be relying on the use of ITS or not, and if so if ITS services should be provided to the driver, the vulnerable road user or both. Services that alert or inform children and elderly of a danger need to take the ability of those road users into account when designed and developed, introducing characteristics, which are attractive and user-friendly. The functionality of such systems could also affect pedestrian and cyclist behavior in a negative way. For example, the provision of such systems may lower the VRUs natural scanning for dangerous situations and thus lead to lower “alert” levels.

The speed of the vehicle involved in a collision is a determining factor for both the chance of an accident, and the severity of an accident involving a VRU. Examples of devices that have as a goal to reduce speeds include speed humps and other traffic-calming measures, speed-measuring systems with feedback to the driver on roadside displays, in-car systems that remind the driver of local (legal or advised) speed limits, and in-car systems that intervene to reduce the speed when someone tries to exceed the legal speed limit.

In-car systems that remind the driver of local (legal or advised) speed limits can be of different types. It is not surprising that audible warnings are recommended over visual ones. People react the quickest to touch (tactile message), second quickest to what they hear (audible message) and the slowest to what they see (visual message). This is obvious. Think about being at a busy location such as in an airport terminal, and someone touches your shoulder, someone calls out your name, or someone holds up a sign with your name. What would you be most likely to react too quickly? That audible messages are more effective than visual ones is probably true especially for children. VRUs can be warned on a device they carry with them. Such devices could be vibrating and give a tactile signal as well as an audible one.

Setting the legal speed limit to be “safe” is equally important. It has to be defined what “too fast” means when children and elderly are adjacent to or in traffic walking accompanied by and adult (Johansson and Leden, 2010). That preschool children should not encounter cars in their play areas or where they walk. Actual vehicle speeds should be below 20 km/h where children ages 7 to 12 years are crossing a street, especially if they are walking unaccompanied by an adult. This speed is often called human-powered speed, and is used in the context of “shared space” and areas marked by road signs such as “residential area.” Children above age 12 years should not cross at locations where motor vehicle speeds exceed 30 km/h. This applies to routes to school, to leisure activities, and when visiting friends. Elderly often have sight and/or hearing impairments and they move slower compared to other age groups, and sometimes they have mental-processing impairments. Therefore, older people are often as vulnerable as children. Also for adults, the actual vehicle speed should be a maximum of 20 km/h where there is a high risk of collision between vehicles and unprotected road users, for example at high volume unsignalized locations. In general, the accepted maximum safe speed where there are bicyclists mixed with cars is 20–30 km/h (Kröyer, 2015). To secure travel speeds below 20 km/h, additional measures like ISA or camera enforcement of speeds near crossing points might be needed.

Further development of intelligent “platforms,” such as speed-activated trapdoors type Edeva, is another option to secure safe speeds of 20 or 30 km/h. Ideally, a street should have a speed-reducing device that is clearly felt by drivers going above the desired speed but the street should be kept flat and comfortable for road-users traveling at or below the desired speed. This is of special benefit to standing passengers in buses and to patients traveling in ambulances.

More futuristic examples of ITS could be based on holograms aiming at shaping virtual areas or “walls.” A more conventional example of this idea is shown in Fig. 1. The virtual area is shaped with two stop lines: the first 10 m before and the second adjacent to the crosswalk. In this case, the “wall” is shaped by road markings on the ramp on an elevated crosswalk. The impression of a wall could be further developed, for example, using holograms or LED-lights to emphasize the vertical dimension and to alert about crossing VRUs.

At approaches with two lanes or more, multiple-threat conflicts occur due to vehicles overtaking stopped ones in the adjacent lane. These conflicts are a threat especially to children, as they often are hidden behind the stopped vehicle, if it has stopped close to a crosswalk. Advanced yield bars or stop lines at a distance to the crosswalk of about 10 m is recommended to alert drivers to stop and not to overtake a stopped car or truck in the adjacent lane, when a VRU is crossing (Fisher and Garay-Vega, 2012; Leden et al., 2018). However, installing yield or stop lines is not yet an option available in many countries. For example, according to Finnish and Israeli regulations among other countries, yield or stop lines cannot be installed except for at signalized crosswalks, though such lines are

Figure 1 Crosswalk protected by a virtual area and “wall” in Playa de las America, Tenerife.

already used at nonsignalized crossings in, for example, Spain, Japan, and the United States. ITS systems such as Collision Avoidance and Warning Systems and Pedestrian and Cyclist Detection System with Emergency Braking are also feasible for alerting drivers to stop and to stop early, and not to overtake a stopped car in an adjacent lane.

Feeling Confident and Secure (To Leave Home and Walk and Cycle)

Personal safety and security should be an obvious right in any civilized society; and a person's, or their parent's, fear of them having an accident or being assaulted is one of the limiting factors for leaving home to walk and cycle. In most communities, there is a higher risk of being injured in a traffic accident than from an assault. However, in some cities, the risk of becoming a victim of crime is greater than the risk of dying in a traffic accident. Children and elderly equipped with a mobile phone can call for help. Streets having video cameras or speed cameras monitored by police can improve the confidence and security even more.

Another important issue to feel confident is the design and equipment of the bike itself, an upright seating position and a low bike frame making it easy to climb on and off the bike. Some equipment facilitating turning left would be useful as many senior citizens have a stiff neck and bad balance, and are significantly ($p = 0.0012$) more involved in crashes when intending to turn left compared to other age groups. A rear-view mirror could help, as stated by senior cyclists, but improvements are also possible by designing the infrastructure, so that it becomes unnecessary to merge with motor vehicles when turning left.

Guidance (Leading or Navigating)

There are many ITS solutions that can be used for guidance (leading or navigating). For navigation, we can distinguish between two groups of devices: those based on GPS and others, the latter are normally used to complement the first in order to improve their accuracy getting a seamless positioning. The experts answering the questionnaire at the Velo-city 2007 conference mentioned two main potential guidance applications: Safe Route Guidance and Safe Crossing Guidance through warnings. Half of the experts that expressed an opinion (five out of 10) stated that route guidance systems, advising people about their safest choice, would improve safety at least for adult VRUs.

Almost all experts suggested a digital map for online route guidance when cycling, and also for trip planning before the trip starts. On-line devices like Personal Digital Assistants (PDAs) could also be used, for example, to get local weather information or to find time tables for public transport and especially to see whether it is allowed to bring the bike on a train, tram, or bus. A special design of the devices making it easy for elderly to use them was considered crucial. The following automatic types of equipment for bikes were considered important to test and further develop: automatic locking and opening, for example, at a distance by using the key as for cars, automatic gears, automatic turning on and off of bicycle lamps (with power supply from a reliable dynamo), and automatic elevating of the saddle after mounting.

Child or other VRU route might take them to a dangerous crossing point. Seven out of 10 experts suggest that VRUs are given route directions, on a GPS or cell phone, to have them walk/bike around crossing points that are dangerous with respect to vehicle traffic. But there are alternatives to avoiding dangerous locations. The crossing points can also be made less dangerous with the use of technology. Six experts suggest that streets should have video cameras that process images of objects and people in a street, and, if a child is detected, in-vehicle alarms are triggered in nearby vehicles. Five experts suggest that children carry emitting devices with signals picked up by a detector in the vehicle and that an alarm is triggered. This can either be done whenever a child is within X meters from the vehicle, where X can vary with vehicle speed (3 experts) or dangerous proximity can be determined by a GPS device when a child is already in the roadway (2 experts).

A different strategy than avoiding dangerous crossing points, or mitigating their danger, is to change the child's destination. This can obviously not always be done, but rather than trying to find the safest way to the closest convenience store or bus stop, maybe there is another one slightly further away that can be reached in a safer way, and quicker than the nearby one when following safe routes.

Getting Contact with and/or Being Localized

GPS systems permitting a person to establish contact are useful from a safety perspective especially for demented elderly people, who suddenly do not know where they are. Such systems can enable relatives to localize them. There are systems that send out SMS

messages to all designated contacts with the user's exact current position. But for children and older people in general, a regular mobile phone is by most experts regarded to be more than enough.

ITS Improving the Safety of Cyclists

Within the VRUITS project, a list of 23 ITS was drawn up (Silla et al., 2017). This included all ITS that were deemed to be near to market and to have good potential for improving the safety, mobility, or comfort of VRUs. Based on a multi-criteria analysis in the VRUITS project, five systems were estimated to have a large effect on improving the safety of cyclists. Intelligent Speed Adaptation, ISA, of cars would be the most efficient measure to provide a safe environment, if enough political support is available to implement the measure and ensure safe speeds. Recently, this seems to be the case in the European Union with suggestions to mandate ISA on new model cars starting in 2022. However this was not the case when the list of 23 ITS was drawn up.

Below follows a short description of each assessed system. We can distinguish between two kinds of systems dependent on whether the detector is mobile (goes in the vehicle/mounted on pedestrian/cyclist clothing) or fixed.

Blind spot detection (BSD) uses vehicle sensors to detect pedestrians, cyclists, and mopeds in blind spots near cars, trucks, and buses. The system addresses mainly the side areas of the car/truck/bus, but optionally also the front and rear of the car/truck/bus. After a detection, the system provides a warning to the driver. The system does not intervene. The system aims to prevent accident between cars, trucks, and buses and VRUs in the blind spot of the car/truck/bus. Note that the blind spot can be on either side of the vehicle (Fig. 2).

A *bicycle to vehicle communication (B2V)* system informs and warns the car driver about cyclists on the road in the vicinity of the car/truck/bus, and the cyclist of potential collisions with nearby cars/trucks/buses. Both the car/truck/bus and the cyclist need to be equipped with a cooperative device to send and receive messages with cyclists, and with a GPS device to determine the relative locations. Cyclists can receive information on their mobile devices (e.g., smart phones). The system does not intervene. The system aims to prevent all accidents between cars/trucks/buses and cyclists due to inattention of car/truck/bus driver or cyclist. All these road users need to be equipped for the system to work well (Fig. 3).

The *intersection safety (INS)* system assists drivers and vulnerable road users in avoiding common mistakes which may lead to typical intersection accidents. It covers the functions left- and right-turning assistance and vehicles arriving perpendicular to VRUs. Left- and right-turning assistance concerns the case where a vehicle is turning left or right into the path of the VRU. A roadside unit (RSU) detects the VRU crossing or approaching the intersection via camera or radar, assesses the risk of a collision, and sends a warning of a potential collision to the vehicle. The vehicle driver is informed or gets the warning via an on-board unit, depending on the urgency of the situation. The roadside infrastructure also informs the VRU of the danger by, for example, flashing lights and/or sound.

Vehicles arriving perpendicular to a VRU concerns the case where the vehicle drives perpendicular to the path of the cyclist. The process is the same as for the first function: an RSU detects the VRU crossing the intersection and informs the vehicle about the possible collision with the VRU. The system depends on short-range communication and roadside sensors. Optionally, the vehicle

Figure 2 Blind spot detection (BSD).

Figure 3 Bicycle to vehicle communication (B2V).

Figure 4 Intersection Safety (INS).

Figure 5 Pedestrian and cyclists detection system + emergency braking (PCDS + EBR).

also uses its own sensors. The system does not intervene. The system aims to prevent accidents between cars/trucks/buses and VRUs at signalized and nonsignalized intersections (Fig. 4).

Pedestrian and cyclist detection system can be combined with *Emergency braking (PCDS + EBR)*. PCDS + EBR is a vehicle built-in system which is aimed at preventing or reducing the severity of vehicle-pedestrian/cyclist crashes by using detection sensors that will detect pedestrians/cyclists in front of a forward-moving vehicle (also known as Automatic Emergency Braking [AEB]). If a crash is likely, the system warns the driver and if the driver fails to respond in time and the collision risk remains, the system will intervene through automatic braking. It is assumed that the system will prevent accidents in which the drivers would not have observed the pedestrian/cyclist otherwise or would not have reacted in time. Therefore, the system will mainly prevent the accidents related to the inattention of car drivers. For speeds up to 35 km/h, the system is considered to be able to prevent collision; for higher speeds (up to 50 km/h), the system should reduce the impact of the vehicle-pedestrian/cyclist crashes by reducing the car speed (Fig. 5).

The *VRU Beacon system (VBS)* consist of a tag or device carried by a VRU that sends out a signal, which is subsequently detected by a receiving device installed in vehicles. This system calculates the trajectories of the detected VRU in relation to the vehicle trajectory and assesses the possibility of a collision. The driver is then warned about a potential collision without any active intervention. Targeted vulnerable road user groups are pedestrians and bicyclists as well as Powered Two-Wheelers (PTWs). The VBS system detects not only persons/vehicles in front, but also those at the rear and side of the vehicle. The VBS system is also able to detect possible collisions when there is no line of sight between vehicle and VRU. Scenarios, which VBS is mainly addressing, are critical situations in urban areas, where motorized traffic is traveling at speeds up to 50 km/h, where obstructed views or unexpected behavior of VRUs can potentially lead to conflicts. The system aims to prevent accident between cars/trucks/buses and vulnerable road users (Fig. 6).

Conclusions: Result of Safety Impact Assessment

The author together with colleagues explored the safety impact of systems, which were estimated to have a high potential to improve the safety of cyclists, especially: Blind Spot Detection (BSD), Bicycle to Vehicle communication (B2V), Intersection safety (INS), Pedestrian and Cyclist Detection System + Emergency Braking (PCDS + EBR), and VRU Beacon System (VBS).

Figure 6 VRU beacon system (VBS).

The main results of the assessment showed that all investigated systems affect safety of cyclists in a positive way by preventing fatalities and injuries. The estimates considering 2012 accident data and full penetration showed that the highest effects could be obtained by the implementation of PCDS + EBR and B2V whereas VBS had the lowest effect. The estimated yearly reduction in cyclist fatalities in EU-28 varied between 77 and 286 per system. A forecast for 2030, taking into accounts the estimated accident trends and penetration rates, showed the highest effects for PCDS+EBR and BSD.

The results of this study show that the selected ITS have a high potential to improve the safety of cyclists. It should be noted that the impact depends on the penetration rates. Therefore, in order to realize the potential safety effects the deployment of most promising systems should be supported by different stakeholders and decision makers. As indicated earlier, our estimates include some uncertainty. Therefore, in order to improve the accuracy of the estimates, there is a need for better accident data (on number and details of the accidents; including also hospital records) and trials to test the functioning of the systems and their effect on road user behavior.

Introduction

While there is no accepted definition of bicycle infrastructure, most persons consider it to be the improved travel way or the transportation facility upon which the bicyclist operates their bicycle. Infrastructure can also include support facilities such as bicycle racks, bicycle repair tool stations, and facilities to support sharing or short-term rental of bicycles. This article does not address primitively improved trails and terrain that are used for mountain bicycling, a popular recreational activity.

History of Bicycle Infrastructure

The bicycle evolved into today's shape and function in the late 1800s, when it was known as the safety bicycle. It quickly surged into popularity as a significant device for urban mobility and recreational travel soon after this date. It was affordable, safe and simple, fun to operate and maintain, and provided faster transport speeds than walking or horse-drawn transportation. This boom in bicycling contributed heavily to good roads movements in many countries. Bicyclists were among the first to advocate for paving of dirt and gravel roads and pathways to provide smoother all-weather surfaces for riding. These paved roads became the earliest forms of bicycle infrastructure, but this effort was occurring prior to the popularization of automobiles (Reid, 2015).

This bicycle boom turned into a bicycle bust by the mid-1920s in North America and in the 1950s in Western Europe. Adult urban bicycling became overwhelmed by availability, convenience, and comfort of affordable automobiles. Safety for bicyclists became compromised by collisions with cars, and bicycling was reduced to a recreational activity or a child's toy for the next 50 years in the United States and countries.

From 1920–70, specialized infrastructure for cycling in cities and other areas was largely nonexistent throughout the world. But a continued strong tradition for adult bicycling for transportation persisted in much of Scandinavia and in the Netherlands. In the 1960s, key northern European cities began to construct high-capacity transportation facilities resembling the United States freeways and high-capacity urban highway systems. These efforts to carve wide space for highways through established cities met strong local resistance, and bicycling advocates joined in opposition, in part, due to the increased dangers caused by rising automobile usage in city centers. As an alternative, bicycle advocates pushed for the development of specialized bicycle infrastructure that would allow safer bicycling in the city center as well as for more pleasant rural excursion riding. Since this time, bicycling infrastructure has been introduced and enhanced in much of Northern Europe, led by the Netherlands and its many cities, plus Copenhagen and other Scandinavian countries. Today, Copenhagen claims the largest daily bicycle commuting mode share of any Western city, and the Netherlands has the highest rate of any developed country. Figs. 1 and 2 show typical examples of bicycle infrastructure in Amsterdam and Copenhagen. While there are a variety of factors involved, the commitment of these communities to provide a comprehensive network of bicycle infrastructure gets much of the credit.

European bicycle capitals take varying approaches in developing bicycle infrastructure, but they are generally built around providing physical separation between bicyclists and motor vehicles, where appropriate and possible. Drivers and bicyclists are generally planned and expected to share road space only on low-speed, low-volume roadways. In addition, bicyclists may be separated from pedestrians, especially in densely developed or commercial areas. Where an urban roadway provides separate physical space each for motor vehicles, bicycles, and pedestrians, the area devoted to bicycles was defined or translated into English as a cycle track (The United States has also used the terms separated bikeway or protected bikeway for similar facilities). Complete European networks are also supported by bicycle trails or paths that are isolated from or placed away from motor vehicle traffic.

Figure 1 Amsterdam.

Figure 2 Copenhagen.

Embracing bicycle infrastructure was much slower to come to the United Kingdom, southern Europe, and North America. In the early 1970s, a few US college campuses began to explore the concept of developing a network to facilitate bicycling on or near their campus. The college town of Davis, California, is credited with the invention of the bicycle lane in 1968. Similar facilities may have existed in Europe at the time, but the US concept of a bicycle lane, providing separation by a painted stripe on the pavement for a wide variety of roadway speeds, traffic volumes, and access conditions, represented a departure from the European approach of physical separation.

The reluctance in the United States to introduce bicycle infrastructure comparable to Europe is often attributed to the efforts of a single individual, John Forester. He was a successful professional bicycle racer who appreciated the opportunity to ride bicycles at high speeds that could be achieved most comfortably on wide traffic lanes that were intended for cars, typically 12 feet (3.6 m). He became concerned that bicyclists might be legally forced to ride in separate “inferior” bicycle infrastructure that did not facilitate bicycle-racing speeds. He developed and popularized a bicycle riding technique in a book, *Effective Cycling*. The method was built around educating bicyclists to take control of travel lanes developed for automobiles. His teachings advocated riding in the center of the automobile lane and forcing motor vehicles to pass by changing lanes. His technique was embraced by many members of the United States League of American Wheelmen who developed classes to educate novice cyclists in its usage (Forester, 2012).

Forester and company became strong advocates against bringing European infrastructure to the United States, and their members dominated many US standards developing organizations. Forester’s philosophy was strongly opposed to bicycle lanes and to physically separated facilities that were located so close to roadways that bicyclists might be prohibited from using the nearby roadway. His teachings and methods may provide for safer operation of bicycles in a traffic environment that provides no separate accommodation for bicycling, but the technique does not appeal to most casual or inexperienced bicyclists. A similar pattern of evolution may also have occurred in the United Kingdom over the same time period.

By the mid-2000s, bicycling was rising to become a substantial component of urban transportation in the leading European bicycle capitals where high quality infrastructure was being provided. Copenhagen claimed that approximately 50% of all commuter trips were by bicycle, and the college town of Groningen, NL, claimed a mode share of over 60%, while most US cities were typically

Figure 3 Montreal.

under 1% and Davis saw the highest rate of any US city, at about 25%. Enthusiasts felt that the European approach to infrastructure with its emphasis on separation may be a strong causal factor.

While bicycle infrastructure development stagnated for decades in most of North America, Montreal, Canada, became the first North American city to begin to import bicycle infrastructure that was similar in design to Europe. Facilities resembling cycle tracks began to appear in Montreal by the early 1990s, and bicycle commuting and recreational usage became the highest of any large city in the United States or Canada (**Fig. 3**).

The US cities, led by New York City, began the process of importing European design principles and adapting them to the United States conventions, beginning in about 2005. Ninth Avenue in Manhattan became the first European inspired bikeway to be constructed in the heart of a major US city, using advice provided by Gehl Architects, a prominent international architecture and planning firm based in Copenhagen. New York continues to be among North American leaders in the deployment and perfection of the United States bicycle infrastructure (**Fig. 4**).

Many other large US cities followed the lead of New York and began introducing bicycle infrastructure in their city centers and key access routes. Canadian cities followed the lead of Montreal, and bicycle infrastructure began to spread quickly through other areas

Figure 4 NY City.

Figure 5 Seattle.

Figure 6 Budapest.

of Europe and the United Kingdom (Fig. 5). This trend continues today, and bicycle usage is found to increase with the provision of improved infrastructure virtually everywhere that it is introduced (Figs. 6 and 7).

Forms of Infrastructure

The United States has traditionally divided bicycle infrastructure into 3 classes, as defined by the American Association of State Highway and Transportation Officials (AASHTO) Bikeway Design Guide. (AASHTO, 2012). Class I facilities are defined as bike paths or trails, which are physically isolated away from roadways that serve motor vehicles. They are often built along levees, waterways, or abandoned railroad lines. They are typically 8 feet (2.4 m) wide and work best when wide enough for pairs of bicyclists to pass each other while moving in opposite directions riding side-by-side (Fig. 8). Rural bicycle trails can become popular tourist recreational facilities, and economic benefit studies for long rural trails show great promise. Urban trail networks are often found in communities with higher bicycle usage. They provide comfortable riding conditions for most users except when they become crowded with pedestrians and other users or when they have poorly designed crossings of busy roadways. But opportunities to introduce trail systems within built up communities can be limited, and they will not support increase in bicycle commuting, if they do not connect with desirable origins and destinations.

Class II facilities are known as bicycle lanes. These are areas of the roadway that are defined by striping in the street to provide limited separation from other vehicles. They can be striped next to the edge of the roadway or can be placed between motor vehicle travel lanes and parking lanes. They are minimally 5 feet (1.5 m) wide and are more comfortable to use when wider, but motorists may mistake them for automobile travel lanes when they exceed 8 feet (2.4 m). They can use a green coating, but coloring is not required by the US standards. It is generally accepted that bicycle lanes work best when placed on low-speed roadways and on roadways that do not allow auto parking (Fig. 9). Bicycle lanes can be found on many high-speed roadways, but users do not find them attractive in these settings, and they seldom produce increased bicycling usage.

Figure 7 London.

Figure 8 Bike trail.

Figure 9 Green bike lane.

Figure 10 Bike Blvd.

Class III facilities are known as bicycle routes. They are minimally roadways that also allow automobile to travel in the same space. The signs provide guidance to bicyclists and advise motorists to expect bicycle usage. They work best on quiet residential streets, but bicycle route signs have been posted on high-speed rural highways to provide for long distance bicycle travel. There are no design specifications for a Class III facility, so a wide variety of quality can be expected.

Trends in bicycle infrastructure have developed tools to enhance Class III facilities. The shared lane marking, or sharrow, is a pavement marking developed in the United States and placed within the center of the travel lane to advise motorists of bicycle activity and to encourage bicyclists to ride toward the center of the roadway. These markings were advocated by Forester and company. They are not popular with other cycling groups who advocate for strong infrastructure. They are mostly used on roadways with speed limits of 35 mph (or 50 km/h) or less.

The bicycle boulevard is another adaptation of the Class III facility. These are typically low volume residential streets that use traffic calming techniques to slow or discourage motor vehicle traffic, while optimizing the route condition for bicycling, in part by minimizing the use of stop signs. These routes tend to be popular to a wider audience of bicyclists, but city street systems can provide only limited opportunities to implement them. Portland, Oregon, and Vancouver, Canada, both have extensive networks of bicycle boulevards that have helped those cities to achieve higher than average bicycle commuting. These facilities are also known as neighborhood greenways in some communities. The bicycle boulevard concept can also be found in Europe, as shared streets or auto-free zones (Fig. 10).

Facilities comparable to European Cycle Tracks have not appeared in the most recent versions of the AASHTO guide, and this may explain in part the low rate of evolution of bicycle infrastructure in the United States. But this is expected to change in 2020 when the next edition of the AASHTO Bicycle Design Guide is planned to be released. The United States Class I, II, and III system has some recognition in Canada, but the bicycle trail, lane, route terminology is more widely used, and the design of facilities is generally like the US facilities meeting these class descriptions also can be found in Europe, but European guidance for when to best use these treatments is stronger and more precise. It discourages bicycle lanes when traffic volumes or speeds exceed specific thresholds.

Consideration for European Design Approaches

There is not agreement among leading European communities on a single best way to design a facility, but it is generally agreed that North American guidelines are primitive or inferior to European practices. The *Crow Manual*, a bicycle design guide published in the Netherlands, is a commonly used and respected design guide for applying European approaches (CROW Platform, 2016). The NACTO Bikeway Design Guide and other publications by the US National Association of City Transportation Officials (NACTO, 2014) are among the most widely recognized bicycle guides in the United States, but new publications on the subject are being completed regularly.

A tour of Europe reveals a wide variety and evolution of bicycle infrastructure as communities move from systems that were built for two travel modes, cars and pedestrians, to infrastructure that supports bicycling as a third mode. Some communities have bisected wide sidewalk areas to create an area for cycling and an area for walking, using paint or textures, as a first step toward dedicated bicycle infrastructure. Others have widened their sidewalks or constructed a new pathway area between the sidewalk and the roadway for use by bicyclists (Fig. 11).

Communities with the most experience and highest bicycle usage have generally developed design approaches that reconstruct the area of roadway to be occupied by bicyclists. They have developed intersection traffic management strategies that reduce or limit conflicts between motorists and bicyclists, often featuring roundabouts or bicycle traffic signals. They have also developed roadway design features that were crafted to address safety issues apparent in the older and more primitive designs.

A typical cycle track in the Netherlands is typically at least 2 m wide (6.5 feet) and may be separated from both the motor vehicle travel way and the sidewalk by planting strips to clearly delineate the facility. Parked cars may be found on the street side, but a raised curb is virtually always provided between the parking lane and the bikeway. Also, the bikeway surface uses red pigmentation to

Figure 11 Paint on sidewalk.

Figure 12 Plastic posts.

differentiate it from other areas of the roadway. This design approach is well suited to new development outside of the traditional city centers. Opportunities to provide this treatment may be found for routes in or near city centers, where roadways may have been widened in the 1960s to provide more travel lanes but repurposed years later to provide dedicated cycling space. In developed areas with limited space, cycle tracks are typically one way and provided on each side of two-way roadways. They can be provided as two-way facilities in more suburban environments where cross traffic is lower, and access is infrequent.

An evolution toward European configurations is visible in the United States and Canada, where many facilities use temporary plastic traffic posts and pavement marking to introduce separation. This treatment is economical, and some communities have been willing to provide temporary facilities as a demonstration test to see if the facilities will induce bicycling and not severely affect motorized traffic (**Fig. 12**). Over next 20 years many of these temporary looking facilities will likely be reconstructed with more permanent features to more closely resemble the best European facilities (**Fig. 13**).

Level of Stress Classification System

A different set of characteristics for classifying bicycle infrastructure is growing in popularity. It is based upon the level of stress or comfort felt by bicyclists when they use a facility, and not as much by its physical characteristics ([Mekuria et al., 2012](#)). Ranging from LS (Level of Stress) -1 to LS-4, it is a measure of how users will rate a facility. LS-1 facilities provide a comfortable and quality experience for all users and may encourage more persons to travel by bicycle. These can include separated facilities, paths, and bicycle boulevards. LS-4 facilities are generally not found attractive to most potential users. Many existing bicyclists will not use them, and they can discourage novice users from becoming regular users. Bicycle lanes on quiet streets can be rated LS-2, while bicycle lanes on busy, fast streets are rated LS-3.

Figure 13 Redondo Beach bikeway.

Figure 14 Cycle snake bridge.

Communities that are concentrating on building or upgrading facilities to LS-1 or LS-2 are generally finding that bicycle usage rises with the coverage of the network. The low stress facilities may have special designations, such as an All Ages and Abilities (AAA) network. A bicycle mode share of 10% of commuting trips may be reasonable where a grid of low stress facilities allows cyclists to ride comfortably to most destinations within 3–5 miles (5–7 km).

While many communities have been nervous about trading space between automobiles and bicycling, separate and new infrastructure for bicycling (and walking) is seeing substantial investment. Many bridges over roadways and waterways have been funded primarily for semi-exclusive use by bicyclists. Well-known examples include the Hovenring in Eindhoven NL, the Cycle Snake in Copenhagen, and two bicycling bridges in Calgary, Canada. Funding has been set aside for other ambitious projects, and many will likely to become landmarks when completed (**Figs. 14 and 15**).

Bicycling and Safety

Bicyclists are vulnerable road users. Riders can be susceptible to injury and death when struck by motor vehicles. Safety considerations have governed and regulated the evolution of bicycle infrastructure in many countries. Studies of early European cycle tracks suggested that they might not be as safe as other types of bicycle infrastructure. More modern designs have probably addressed concerns over the rate of occurrence of incidents, especially for bicyclists traveling at high speeds, but any potential for a death or serious injury can raise questions.

It is widely accepted that bicycling can produce health benefits, and economic studies have suggested that these health benefits greatly outweigh travel injury risks. Also, the rate of incidence of serious injury or fatality while cycling, even in automobile traffic, is comparable to the rate of incidence of driving automobiles, if measured per hour or per trip. Finally, studies have suggested that

Figure 15 Calgary bridge.

cycling may benefit from “safety in numbers.” As the number of cyclists increases, collision rates between cyclists and other road users’ trend downward. This effect has been confirmed across countries and cities, but it has not been studied as extensively as cycling increases in a specific community. Part of this effect is explained by motorists and cyclists adjusting their behaviors as they more regularly interact with each other. Another factor could stem from an overall reduction in motor vehicle travel compared to population.

Other Bicycle Infrastructure

Communities that wish to encourage bicycling have generally found the importance of having attractive and comfortable bikeways that can be used for most short trips. But other infrastructure is often needed to encourage growth in bicycling. Perhaps highest in importance is bicycle parking. Bicycle racks or storage space must be convenient, functional, and plentiful. Careful and proper planning for bicycle parking minimizes the potential for bicycle theft and keeps the urban environment orderly. Train stations in key European capitals can offer parking for 1000’s of bicycles. These can include underground facilities where users can check in their bicycles with an attendant for maximum security.

In the United States, where bicycling has not risen to levels seen in Europe, many programs to integrate bicycling with transit are in place. These include bicycle racks on buses and areas on trains dedicated to carrying bicycles with their owners. The ability to maintain these programs when bicycling rises to more than 10% of all trips may be difficult in the future.

Lack of access to a bicycle is also a limitation to increases in bicycling. Short-term bicycle rental (bike sharing) has been introduced into over 100 cities throughout the world over the past 15 years. Earlier systems required docking of bicycles at specific locations when not rented. In the past 5 years, dockless systems have become more popular (**Fig. 16**). These feature GPS location information and fare payment on the bicycles themselves.

Figure 16 Bike share.

Electrical power propulsion assist for bicycles is also becoming a new factor. E-bikes have become very popular for new bicycle sales in Europe and have attracted new riders who tend to be older or less fit users. E-bikes minimize the effect of hilly terrain and perspiration. They can make commuting more practical for many persons. E-scooters are not considered as bicycles, but their infrastructure requirements are quite like biking needs, and they have grown in popularity very quickly in large cities. Users discovering the added convenience of an electrically powered personal vehicle may migrate from scooters toward E-bikes which are more practical for longer trips.

Biography

Rock Miller is a registered Civil Engineer based in the United States with over 40 years of work experience in Traffic Engineering. He has focused on establishing standards to allow for better bikeway design in the United States and has designed many innovative facilities in California and Alberta, Canada, and has overseen facilities in other states and regions. He has focused on bikeway engineering and traffic safety for the past 10 years, and he has studied European designs to determine how to adapt them to the US practices. Rock is a Past President of the Institute of Transportation Engineers, a 15,000-member North American-based professional association. He is currently a voting member of the US National Committee on Uniform Traffic Control Devices and a member of the Transportation Research Board Bicycle Research Committee.

The Road User, the Vehicle, and the Infrastructure

The users of bicycles are a very heterogenic group. They range in age from toddlers riding small tricycles in front of their homes, to children that use the bike as a toy as well as a travel mode to friends or school, the “regular” cyclist that uses the bike for transportation or recreation, to people well above retirement age still riding for transportation or recreation. Also, the group ranges from the “passive” child passenger in a child seat or a wagon, to cyclists that use the bicycle or tricycle for delivery services, to athletes that use it for training or competitions at high speeds. *The vehicle (the cycle)* also differs. There are child bikes that have lower statue, classical bikes, bikes with child seats (front and/or back), bicycles with child wagon connected at back, tricycles with a box at front or back for children or merchandise, tricycles for adults, mountain bikes, low riding bicycles, racing bicycles, transportation bicycles, and e-bikes. In addition, there are multiple other micromobility devices such as (e-)-kick-bikes, (e-)-skateboards etc. *The infrastructure* is used by different combination of those road users and vehicles, so you can find different combinations or road users on different parts of the road system. There are diverse design solutions, and the solution used varies both between countries and within countries and even between different locations within the same city, creating a complex system for the cyclists to navigate. To ensure a safe cycling, the infrastructure, must allow for those different combinations to fulfill their needs in safe manners, where the traffic situation is a combination of those three elements of the transport system, see Fig. 1.

The Road User, Children and Seniors

When it comes to traffic, and traffic safety, children require special attention. Children’s sight and hearing is not fully developed (DaCoTa, 2012). Their perception of the traffic environment is not always “correct,” and the youngest ones often assume that the other road user is aware of them (DaCoTa, 2012). Young children have a hard time identifying dangerous crossing sites (Ampofo-Boateng and Thomson, 1991), and do not always make safe crossing decisions (Connelly et al., 1998; Plumert et al., 2004), especially at higher speeds (Connelly et al., 1998). Children can also easily be distracted, especially the youngest ones (Demetre et al., 1992), which can cause accidents (Axelsson and Stigson, 2019). It should therefore be clear that, even though their

Figure 1 The three elements of the transport system.

preconditions improve with higher age, it influences young children's ability to safely navigate a complex traffic environment. Another safety related fact is that children are shorter, this means that they are more easily missed by other road users due to obstructions of sight (e.g., parked cars, railings), which is highly relevant for design of the infrastructure. We must accept that we cannot expect a child to perform in as safe manners as an adult, and therefore, adjust the transportation system so that it takes this into consideration.

Seniors is another important group for traffic safety. It is a well-known fact that with higher age, the ability to see and hear deteriorates, the body loses muscle mass and the strength of the bones is reduced. We can even see increased cognitive challenges such as Alzheimer's (Delin and Rudgren, 2007). Seniors also have highly elevated risk of both serious and fatal injuries in collisions between bicyclists and motor vehicles (e.g., Kaplan et al., 2014; Kröyer, 2015a). This creates some challenges. On one hand, we strive to increase mobility and active travel for seniors, this for improved health and quality of life. Simultaneously, by making this group cycle, we are making a relatively fragile group use a travel mode that has considerable risk of injuries and limited safety equipment. Since this group seems to be much more likely to be seriously or fatally injured and is a considerable part of those who suffer from traffic accidents, they need special focus.

The Cycle

The type of cycle has some bearing on traffic safety. There is however, rather limited research available regarding this issue. Rodgers (1997) through self-reported response, showed elevated risk for those (1) who rode an off-road trails opposed to roadways, (2) who rode racing bikes, or (3) all terrain style bicycle, compared to general purpose bikes. There are several aspects where bicycle type might influence the traffic safety, for example:

- **Visibility:** the height and structure of the bicycle relates to the cyclist sight lines and the visibility towards other road users. A low riding bicycle is more easily hidden by other elements of the traffic environment (e.g., vegetation, railings).
- **Crash mechanics:** The height and seating position of the cyclist will influence the crash mechanics. Lower stature is more likely to results in forward projection (i.e., full contact with the front of the vehicle) compared to a higher cycle. If the cyclist is sufficiently low, it might also increase the risk of an overrun accident.
- **The maneuverability and space requirement** differs between different bicycle types. We can also expect that the speed is higher on for example racing bicycles and some E-bikes compared to a box cycle. It should be noted that it is not the average speed of a bicycle trip that is of primary concern, but the speed at the time of the conflict/accident, and especially top speeds coinciding with conflict areas. Therefore, E-bikes that support up to speeds of 25 km/h might move slower downhill than traditional bicycles which often

can reach speeds around 50 km/h in hilly terrain. Higher speeds lead to more difficulty maneuvering the bicycle. Both speed and maneuverability can influence the risk of an accident.

- *Speed* is paramount for injury severity in accidents. It is well known that the speed of the motor vehicle that hits bicyclist influences the injury severity (Rosén, 2013). However, there is limited research regarding how the speed of the cyclist themselves influences the injury severity.
- *Weight*: We can speculate that the combined weight of the cycle and the cyclist is likely to influence the physics of the crash mechanism, we can speculate that this will mainly influence collisions between unprotected road users.
- *Other properties* such as braking, stability, center of weight, lights, reflection, and acceleration of e-devices can be expected to matter.

The Infrastructure

The infrastructure design influences the need for interaction as well as under which conditions this interaction is performed (e.g., speed, visibility) and thereby the risk of an accident occurring. The design itself can also create risks, for example, risk of a fall, collisions with rigid object, etc. The safety of the infrastructure is highly dependent on the design (e.g., Elvik and Vaa, 2004). There are several options to improve the safety of bicyclists through design of the infrastructure. Since that the traffic safety effects of different infrastructure measures cannot be adequately discussed in a short chapter, we refer the reader to other more comprehensive literature.

The Accidents

Bicyclist related accidents can be divided into the following five groups:

1. Collisions with motorized vehicles
2. Single accidents
3. Collisions with other bicyclists/mopeds
4. Collisions with pedestrians
5. Other collisions (e.g., animals, open doors)

The most frequent accident type are single accidents. Single accidents are often around 46%–94% of all reported bicycle accidents (Amoros et al., 2012; Boufous et al., 2011; Davidson, 2005; Eilert-Petersson and Schelp, 1997; Konkin et al., 2006; Niska and Eriksson, 2013; Scheiman et al., 2010; Simpson and Mineiro, 1992; Tin Tin et al., 2010, one study, Martínez-Ruis et al., 2013, showed lower percentage, probably due to underreporting). Among children, single accidents are in the range of 67%–94% of all bicycle accidents (Axelsson and Stigson, 2019; Boufous et al., 2011; Eilert-Petersson and Schelp, 1997; Simpson and Mineiro, 1992), the proportion of single accidents was somewhat higher among the youngest compared to older children (Axelsson and Stigson, 2019; Simpson and Mineiro, 1992). Collisions with motor vehicles constitute often between 2% and 45% of all bicycle related accidents (Amoros et al., 2012; Boufous et al., 2011; Davidson, 2005; Eilert-Petersson and Schelp, 1997; Konkin et al., 2006; Niska and Eriksson, 2013; Rosenkranz and Sheridan, 2003; Siman-Tov et al., 2012; Simpson and Mineiro, 1992; Tin Tin et al., 2010). Among children, the similar proportion are 1%–28% (Axelsson and Stigson, 2019; Boufous et al., 2011; Eilert-Petersson and Schelp, 1997; Simpson and Mineiro, 1992), somewhat lower among the youngest groups, but increased to 12%–28% among the older child groups (Axelsson and Stigson, 2019; Simpson and Mineiro, 1992). The data seems to indicate that the majority of the bicycle related accidents are single accidents, as well as the majority of the serious injuries (Niska and Eriksson, 2013; Weijermars et al., 2016). A study by Gårder (1994) of hospitalization in Maine showed that 35% of bicycle crashes leading to hospitalization involved motor vehicles and 65% were single-bicycle accidents.

However, the former required an average hospital stay of 9.2 days and the latter only 4.6 days, so the two categories account for roughly the same number of injury-days. Regarding fatal accidents, we get a clearer picture, collisions with motor vehicles stands for majority of the fatalities, often in the range of 64%–100% of all cyclist fatalities (Bil et al., 2010; Nicaj et al., 2009; Rowe et al., 1995; Rosenkranz and Sheridan, 2003).

There is far less known regarding other accident types. Collisions between two or more cyclists (or cyclists and moped drivers) have been shown to account for 1%–11% of all bicycle accidents (Davidson, 2005; Boufous et al., 2011, 2012; Eilert-Petersson and Schelp, 1997; Niska and Eriksson, 2013; Simpson and Mineiro, 1992), and 4%–8% of child bicycle accidents (Axelsson and Stigson, 2019; Boufous et al., 2011; Simpson and Mineiro, 1992). Studies of collisions between bicyclists and pedestrians indicate that those collisions make up around 1%–2% of bicycle injury accidents (Boufous et al., 2011; MSB, 2013; Nilsson and Åström, 2016; Tin Tin et al., 2010), and majority of those who were injured in those accidents were the pedestrians (Eriksson et al., 2015; Niska and Eriksson, 2013). Another known risk for cyclists is to collide with an open or opening car door. Those accidents were shown to constitute 3%–9% of bicycle accidents (Boufous et al. 2011; Isaksson-Hellman, 2012; Johnson et al., 2013). There are also cases where this accident type results in serious or even fatal injuries (Nicaj et al., 2009). There is limited research regarding the scope of collisions with animals. A survey-based study showed 3% (urban) and 4% (rural) of the self-reported accidents were collisions with animals (Kröyer, 2016a), this study was however based on people cycling for exercise in competitive ways.

Figure 2 Classification of bicycle-related accidents that were registered in Sweden in 2013 by type and injury severity, fatal accidents are based on accidents registered in 2000–2014. Source: STRADA (2015).

If we take Sweden as an example, then in the year 2013 (injury accidents, police, and hospital registration, STRADA, 2015), 72% of the minor injury bicycle accidents were due to single accidents and a further 7% were due to collisions between bicyclists and/or moped drivers, see Fig. 2. “Only” 18% are due to collisions with motor vehicles. When it comes to the serious injuries, 61% are due to single accidents, and 28% due to collisions with motor vehicles, 7% are due to collisions between bicyclists and/or mopeds, and 4% are due to collisions between bicyclists/mopeds and pedestrians.

Since there were only 27 reported bicycle fatalities in 2013 in Sweden, we use 15 years data, 2000–14 (STRADA, 2015). Of 663 bicycle-related fatalities, at least 16 were pedestrians and 4 were other types of road users (not pedestrians, cyclists, or moped drivers). Also, 59% of the fatalities were due to collisions between a motor vehicle and a cyclist or a moped. 27% and 8% were single accident bicyclists or moped. Around 3% were collisions between bicyclists/moped and pedestrians, were in most cases it was the pedestrian who was killed. Also, 2% and 1% were collisions between two cyclists or a cyclist and a moped driver. Finally, 1% were due to other type of accidents (often related to railway).

Both the literature review and the case sample show that the two first accident types contribute to a great majority of the (recorded) serious and fatal accidents. This means that the main body of the research efforts have been aimed at these accident types. However, not all accidents are reported to authorities. If the accident is not reported it will not be registered in the accident databases, hence it will be missing in the statistics. Bicycle accidents not including a motor vehicle are frequently underrepresented in our accident statistics, and that the more severe the injuries are, the more likely they are to be included into our data (Elvik and Mysen, 1999). We can therefor speculate that there is a large under reporting of the other accident types, and they should also be considered. There are several factors that have been related to bicycle accident and/or the severity of the accidents. Some of those are discussed in the following sub sections.

Accident Location and Time of Year

Bicycle accidents are frequent during months with favorable weather conditions, that is, the summer half of the year especially in countries far away from the equator (Niska and Eriksson, 2013; Rosenkranz and Sheridan, 2003). This is related to that the number of bicycle accidents is strongly related to exposure. One study showed that a considerable part of bicycle accidents occurs during recreation or fitness, while around one in three injury accidents are trips to or from schools (Davidson, 2005). A considerable part of the child bicycle accidents has been shown to relate to trips to and from school (Axelsson and Stigson, 2019), and child bicycle accidents are not limited to residential areas (Abdel-Aty et al., 2007). Many accidents are related to the child using the bike as a toy or for performing stunts, especially among the youngest ones, but also a lack of biking skills, maintenance, or distraction (Axelsson and Stigson, 2019).

Collisions between bicyclists and motorized vehicles usually occur in urban areas (Boufous et al., 2011; Isaksson-Hellman, 2012), but it is there the bicycle exposure is greatest. Some studies however show rural accidents to be more serious

(Boufous et al., 2012; Kaplan and Prato, 2013). Many studies have shown that a majority of bicycle-motor vehicle collisions occur at intersections, often in the range of 51%–90% (Boufous et al., 2011, 2012; Isaksson-Hellman, 2012; Kaplan et al., 2014; Kim et al., 2007; Wei and Lovegrove, 2013). On the other hand, fatalities are frequently reported to have occurred away from intersections, but the proportion of all fatal bicycle accidents varies considerably, 11%–80% (Hoque, 1990; Kim et al., 2007; Nica et al., 2009).

Individual Factors, Age, and Gender

One study showed a higher injury rate for females (Blaziot et al., 2013). Kaplan and Prato (2013) showed that the gender proportions were equal in all injury accidents from collisions with motor vehicles, while other studies (Boufous et al., 2012; Kim et al., 2007; Siman-Tov et al., 2012) showed a majority of those in accidents to be males. The results are more in agreement when it comes to fatal accidents, then males are in a clear majority, often 78%–93% of those killed (Bíl et al., 2010; Kim et al., 2007; Nica et al., 2009; Rodgers, 1995; Rowe et al., 1995), and females have been shown to have a lower risk of fatal injuries (Bíl et al., 2010; Rodgers, 1995). Several studies have shown that young boys are highly overrepresented in bicycle accidents (Axelsson and Stigson, 2019; Boufous et al., 2011; Haileyesus et al., 2007; RNSA, 2014; Siman-Tov et al., 2012).

Sze et al. (2011) showed that children below 14 had elevated risk of severe and life-threatening injuries, however, the difference was not statistically significant due to large confidence intervals. Kaplan et al. (2014) showed children below the age of 10 were more likely to suffer light, severe or fatal injuries in collisions with motor vehicles compared to other children and young adults. There are, however, studies who could not find this difference (Boufous et al., 2012; Rodgers, 1995). As was discussed in the previous section, children have cognitive and physical preconditions that can work in their disfavor. We can also speculate that their travel pattern in the road network is not comparative to those of adults, where several other factors will reduce or amplify possible difference in injury severity.

Accident statistics show seniors to have a highly elevated risk of serious and fatal injuries in collisions between bicyclists and motor vehicles (Bíl et al., 2010; Kaplan et al., 2014; Kim et al., 2007; Rodgers, 1995). This elevated risk seems to start somewhere in the upper middle age years, even as low as from the age group 40–50 (Kaplan et al., 2014) or 55+ (Kim et al., 2007), however, the risk increases dramatically for the older groups (Eluru et al., 2008; Kaplan et al., 2014; Kröyer, 2015a; Sze et al., 2011; Yan et al., 2011). Seniors are also a high proportion of those who are killed in the traffic as cyclists; it varies though considerable between countries (Hagenzieker, 1996).

Vehicle Type

A great majority of vehicle-bicycle collisions are with passenger vehicles (Kaplan et al., 2014; Kim et al., 2007; Simpson and Mineiro, 1992). However, several studies have shown that the risk of serious or fatal injuries is higher if the vehicle is larger, that is, trucks, other heavy vehicle, busses, pickups and vans (Ackery et al. 2012; Eluru et al., 2008; Kaplan et al., 2014; Kim et al., 2007; Moore et al., 2011; Nica et al., 2009; Otte et al., 2012; Yan et al., 2011). Right turns by large vehicles are a serious threat for cyclists, that is, when the cyclists and the large vehicle are coming from the same direction, however, the cyclist is going straight through, while the large vehicle turns right. This is a dangerous interaction due to among other factors the blind spot of trucks, and those accidents tend to be serious when they occur (Pokorny et al., 2017; Richter and Sachs, 2017). In London, freight vehicles were involved in four of ten of all fatal bicycle accidents, and in half of those accidents this was the case (since in London you drive on the left side of the road, it were left turn accidents) (Morgan et al., 2012). The interaction between larger vehicles and cyclists should influence intersection design in particular.

Speed

Speed is a central part of traffic safety. This is due to the simple fact that (a) speed relates to time and distance travelled, hence the time the road users have to react to prevent or to mitigate an accident occurring, and (b), the speed will eventually control the forces that act on the cyclist, hence the injury severity. Collision/impact speed is strongly related to the risk of serious and fatal injuries, where the risk of injuries increases fast with higher speed (Kröyer et al., 2014; Rosén, 2013). Studies have also seen a correlation between both speed limit (Boufous et al., 2012; Kaplan et al., 2014), estimated travel speed (Kim et al., 2007), speeding (Bíl et al., 2010; Kim et al., 2007), mean travel speed (Kröyer, 2015a) and injury severity for bicyclists hit by motor vehicles. The impact speed has also been seen to influence where the head impacts the car in collisions with motor vehicles (Otte et al., 2012). To adjust speed in urban areas is therefore a central measure for bicyclist safety.

Alcohol and Drugs

It is well known that being under the influence of alcohol as the driver of a motor vehicle is a strong risk indicator, and that the risk increases quickly with higher consumption (Forsman, 2013). Several studies show driver intoxication to increase the risk of serious or fatal injuries in collisions between bicyclists and motor vehicles (Kim et al., 2007; Moore et al., 2011). One study used alcohol use for the party at fault instead (that is, either the car driver or cyclist was under influence), that did not result statistically significant difference (Bíl et al., 2010), but the definition might explain the contradicting result.

Part of the cyclists involved in an accidents were under the influence of alcohol (Eilert-Petersson and Schelp, 1997; Kaplan et al., 2014; Kim et al., 2007), however, the proportion was more frequent, 7%–21%, among the fatally injured cyclists (Kim et al., 2007; Nicaj et al., 2009; Rowe et al., 1995). Alcohol involvement was especially frequent in accidents during the evenings and nights (Davidson, 2005; Rosenkranz and Sheridan, 2003). Those who were under the influence of alcohol and/or drugs were more likely to suffer serious (Kaplan et al., 2014; Moore et al., 2011) or fatal injuries (Kaplan et al., 2014; Kim et al., 2007).

Visibility and Road Condition

In the case of a dangerous situation, the road user must understand the situation at hand and notice all critical elements of the situation to be able to decide on measures. To be able to perform this, visibility is important. In intersection collisions with motor vehicles, many cyclists (and probably car drivers) misunderstand the traffic situation and/or make an inadequate plan of actions. Habibovic and Davidsson (2012) showed that the cyclist not seeing the conflicting car due to visual obstruction was a frequent problem.

But it is not only visual obstructions that limit the visibility. Several studies have tried to estimate if the time of day and streetlights influence the number or severity of bicycle accidents. Despite fewer cyclists, a considerable part of fatal bicycle accidents occurs after dark or at dusk or dawn (Rodgers, 1995; Rowe et al., 1995). The risk of serious or fatal injuries have been shown to be higher during night than during daylight conditions if there are no streetlights (Boufous et al., 2012; Kim et al., 2007; Wang and Stamatiadis, 2011; Yan et al., 2011), and Boufous et al. (2012) showed elevated risk during nights with streetlights on. Bîl et al. (2010) showed fatal injuries to be associated with (1) nighttime without streetlights and (2) daylight conditions where the visibility was bad, compared to daylight conditions with good visibility. The study did not show statistically significant elevated risk for nighttime with streetlights. An older study showed that rear-end collisions (where the bicycle was hit from behind) were 80% of the fatal accidents during nighttime, compared to 10% of those during daytime. This study also showed that fatal accidents were frequent when the motor vehicle was overtaking the cyclist and the cyclist swerved out (Hoque, 1990). Those studies further emphasize the importance of good visibility so that the different road users can be aware of each other.

The road condition is also important for traffic safety. First, inclement weather can influence visibility and there is a relation between inclement weather and injury severity (Kim et al., 2007; Wang and Stamatiadis, 2011). Single bicycle accidents are frequently contributed to for example, winter conditions, ice/slipperiness, snow, pavement edge/curbstone, gravel, rigid objects, mechanic failures, speed, distraction and interaction with other road users (Eilert-Petersson and Schelp, 1997; Niska and Eriksson, 2013). Studies have also shown a relation between slippery surfaces and the risk of fatal injuries (Kaplan et al., 2014) and icy roads and injury severity in bicycle-car collisions (Wang and Stamatiadis, 2011). The importance of road condition should not be underestimated, given the fact that single-bicycle accidents are a considerable part of the serious injuries.

Injuries Sustained by Bicyclists

Traffic safety work aims to prevent injuries and the resulting health loss and fatalities. The types of injuries sustained in bicycle accidents is therefore important. Most of the studies that investigate the injuries of bicyclists have shown the following three regions to be the most frequently injured ones.

- Lower extremities,
- Upper extremities,
- Head/neck injuries.

Studies have shown this for: (1) all injury severities except fatalities (Axelsson and Stigson, 2019; Eilert-Petersson and Schelp, 1997; Juhra et al., 2012; Konkin et al., 2006; Maki et al., 2003; Niska and Eriksson, 2013; Otte and Haasper, 2005; Siman-Tov et al., 2012). (2) Single accidents (Amoros et al., 2011; Niska and Eriksson, 2013). (3) Collisions between motor vehicles and bicyclists (Amoros et al., 2011; Haileyesus et al., 2007; Otte et al., 2012). (4) Children (Axelsson and Stigson, 2019; Amoros et al., 2011; Boufous et al., 2011; Olofsson et al., 2012; Siman-Tov et al., 2012). It varies though between studies and injury severity which of those regions are the most frequently injured (there are studies in this list that have shown another body region among the top three).

Head injuries were registered in between 72% and 77% of the fatal injuries (Maki et al., 2003; Nicaj et al., 2009; Rowe et al., 1995), often followed by (but not necessarily in this order) chest, abdomen, torso or neck injuries (Maki et al., 2003; Nicaj et al., 2009). Here, we might add that in collisions with motor vehicles, the cyclists suffers head injuries both from impact with the car and the ground (Badea-Romero and Lenard, 2013), and that the prevalence of brain injuries, soft part injuries and serious head injuries for both children and adults are associated with higher collision speed (Otte, 1989).

Safety Equipment

An effective safety equipment is a good way to reduce the health loss of accidents. They can either be aimed at preventing the accident or to mitigate the consequences. As previously discussed, visibility is important, and there is an association between accident risk and light defects (Martínez-Ruis et al., 2013) and an older study found a high overrepresentation in night-time fatal rear-end accidents where the car driver did not observe the cyclist, where the cyclist was without rear lights (Atkinson and Hurst, 1983). Another study found an association between reflective vest and lower risk of multiparty injury accidents for cyclists (Lahrman et al., 2018). Brake

defects have also been shown to contribute to accidents (Marinez-Ruiz et al., 2013; Scheiman et al., 2010), and controlled tests have shown studded bicycle tires to provide better braking properties on ice (Hjort, 2018), something that might have positive safety effects given the frequent cause of ice/snow as cause for single accidents (in regions where that applies).

Given the importance of head injuries shown above, it should not come as a surprise that the most well known safety equipment of cyclists is the bicycle helmet. Two meta-analysis studies have recently estimated the effect of bicycle helmet. Both studies (Elvik, 2011, 2013; Høye, 2018) showed that the risk of fatal injuries, as well as head injuries and brain injuries was reduced considerably by wearing a helmet. The positive effect is both for adults and children, and in single accidents as well as in collisions with motor vehicles (Høye, 2018). Though general use of bicycle helmet will help us greatly, it cannot solve all serious injuries, since it is unlikely to have any considerable positive effect on serious injuries of other body regions.

Though it is outside the scope of this chapter, the severity of collisions with motor vehicles can also be mitigated by reducing speed, adaptation of active safety equipment, for example, automatic brakes, and measures that make the vehicle more forgiving for the hit bicyclist (inclusive lower share of motor vehicles that are related to more serious injuries).

The Special Case of E-Bikes and Micromobility

Micromobility is used to describe light travel devices that are either man powered or with electric support, where the electricity usually will not support the vehicle at higher speeds than 45 km/hr⁻¹ (ITF, 2020). This includes bicycles, kick-bikes, skates, skateboards, and several other devices. Many of those are new transport modes, and the modal share is currently low. Danish studies show that micromobility devices (exclusive bikes/e-bikes) constituted around 1.5% of the road users on bicycle roads, and 97% of those were e-kick-bikes (Færdselsstyrelsen, 2020). Increased use of those devices can however be expected to result in accidents in the future and we need to start to prevent those accidents before they cause more casualties.

E-Bikes

E-bikes are in many ways similar to a regular cycle; however, they have electric support up to for example 25, 32, or 45 km/hr⁻¹. The speed of e-cyclists has been measured to be somewhat higher compared to a regular bicyclist (Cherry and MacArthur, 2019; Steintjes, 2016), which might increase injury severity in accidents.

Accident statistics show similar patterns compared to regular bicycles. The majority of those injured are males (Papoutsis et al., 2014), females have elevated odds ratio for moderate/serious injuries (Hertach et al., 2018), and head/neck injuries are most frequently followed by injuries to upper extremities, face, chest and abdomen (Papoutsis et al., 2014). Schepers et al. (2014a) showed that when controlled for gender, age and bicycle use, there was an association between electric bicycle use and increased risk of being treated at an emergency department, while among those, the users of electric bicycle were not more likely to be further admitted to the hospital compared to regular bicyclists. Fyhri et al. (2019) also shows elevated risk for e-cyclists, however, similar risk of serious injuries as for regular bikes. Another study showed that some e-cyclists contributed their accidents at least partly to the properties of the e-bike (Hertach et al., 2018). On the other hand, Schepers et al. (2018) showed no difference in risk of injury accidents between e-bikes and regular bikes when controlled for annual kilometers travelled, that is, that study suggest that the reason for difference between e-bikes and regular bikes might be due to travelled distance. Weber et al. (2014) showed diverging results.

The most common e-bike accident type is single accidents (Papoutsis et al., 2014; Schepers et al., 2018; Weber et al., 2014). Dozza et al. (2016) by using naturalistic data showed the most frequent conflict to be with pedestrians, then light vehicles. Krøyer (2019a) studies self-reported conflicts, where single accidents were the most frequent type. Several self-reported accidents/conflicts were attributed to speed, acceleration, road damages or poor road condition, visibility, balance (among others when going on or off the bike), other road user underestimating the speed, crossing curbs, ice/slippery surface, skidding, brake problems, alcohol involvement, interaction, and the weight of the bicycle (Haustein and Møller, 2016; Hertach et al., 2018; Hiselius et al., 2013; Johnson and Rose, 2015; Krøyer, 2019a; Papoutsis et al., 2014). Those factors however also cause accidents among regular cyclists.

There is considerably less research available regarding the safety of e-bikes and e-cyclists and currently, it is hard to draw firm general conclusions if e-bikes are from traffic safety similar, better or worse compared to regular bicycles; more data and research is necessary. The current literature does however not indicate that there is a great difference in the accident statistics, this might though be biased by confounding factors.

Other Micromobility Devices

To evaluate the safety of a given travel mode requires extensive accident data due to the complexity of traffic safety. For this reason, there is much less known about those less frequent travel modes. Konkin et al. (2006) showed that against every 100 cyclists, there were around 10 skateboard user and eight inline skate users reported to an emergency room. As with cyclists, males were in great majority, and 10% respectively 15% were involved in collisions with motor vehicles. Given the recent popularity of e-micromobility devices, we can speculate that this problem has increased and will increase even further as those devices become more popular. A considerable part of the users and those injured are young people and males (APH, 2019; Færdselsstyrelsen, 2020; Stigson and Klingegård, 2020). Those injured in accidents related to e-scooters are mostly the users themselves, but 8%–13% were pedestrians or other road users (Trivedi et al., 2019; Stigson and Klingegård, 2020). Of those, half were hit by an e-scooter, while the rest were cases of fall accidents due to tripping over a parked scooter or lifting/moving a e-scooter not in use (Trivedi et al., 2019). This is in line with ITF (2020) which reported that pedestrians were “only” one in ten of the fatalities.

Single accidents seem to be the most frequent accident type, while collisions with motor vehicle account for 2%–28% of the accidents (APH, 2019; Blomberg et al., 2019; PBOT, 2019; Liew et al., 2020; Stigson and Klingegård, 2020; Trivedi et al., 2019). Majority of the fatalities involved another motor vehicle (ITF, 2020). There have been some estimates of the risk of using e-kick-bikes compared to that of other transport modes (e.g., Færdelestyrelsen, 2020), however, at this point, estimates of accident rate should be taken with some reservations due to data limitations and underreporting.

Head injuries are a considerable problem, but other body regions also suffer injuries (APH, 2019; Kobayashi et al., 2019; Stigson and Klingegård, 2020; Trivedi et al., 2019), and most of the studies report a very low helmet use (APH, 2019; Blomberg et al., 2019; Færdelestyrelsen, 2020; Kobayashi et al., 2019; Liew et al., 2020; PBOT, 2019; Stigson and Klingegård, 2020; Trivedi et al., 2019, one Australian study showed a great majority using a helmet, Haworth and Schramm, 2019), and one study showed the helmet use to be much lower for rental e-kick-bikes compared to self-owned e-kick-bikes (Færdelestyrelsen, 2020). Even though preliminary, this is somewhat concerning results, given the fact that the electric support allows for higher speeds (Cherry and MacArthur, 2019) and APH (2019) reported that excessive scooter speed contributed to 37% of the accidents. In addition, considerable part of the accidents occurred while the road user was under the influence of alcohol, though to a varying degree (APH, 2019; Blomberg et al., 2019; Kobayashi et al., 2019; Trivedi et al., 2019), and ITF (2020) report that many fatal accidents occur during the night.

Those preliminary data indicate that much of the challenges regarding micromobility are “similar” to those of bicycles and e-bikes. Helmet use is however low, and they are somewhat more sensitive to the infrastructure, for example, curbs, potholes, manholes, slippery or low friction, and even malfunctions and balance (APH, 2019; Stigson and Klingegård, 2020). We can also speculate that the interaction is somewhat more complex since the infrastructure is not designed with regards to this road user group and we have not yet established a general code of behavior using those devices. Also, we do not know how the safety of this group is regarding larger vehicles, especially right turn collisions (in countries where people drive on the right). Finally, this is a new travel mode. The users will learn, gain experience, and become better at using it, simultaneously as other road user groups will also gain experience in interacting with those devices. We would like to stress that this discussion is based on very limited accident statistics and research, and therefore subjected to changes in the coming years. This should therefore be taken with considerable reservations.

System View: Exposure, Risk, and Consequence

The state of traffic safety is often determined by counting the number of casualties due to traffic accidents, for example the number of fatalities, or fatalities per 100,000 inhabitants. But, how can we determine the traffic safety from these numbers? Is it acceptable to have 30 bicycle fatalities in Sweden per year, or is it catastrophic? Is it relatively safe to cycle in Sweden or is it dangerous? Is it safer to cycle than to use a car when fatal car accidents are considerably more numerous? To understand this and other factors related to traffic safety, we must consider factors such as *exposure*, *risk*, and *consequence*.

Exposure

Exposure describes how much travel there is, where there is a risk for an accident occurring. (1) Cycling without any interaction with other road users involves the risk of falling or colliding with a rigid object. We might also add that the risk of falling is not necessarily constant, but rather related to the risks we encounter, whether it is a point that is slippery, a badly placed sign that is in the way, or due to moment of lack of attention. (2) Interaction with other road users includes a risk of being involved in a collision or to fall in the efforts of preventing a collision.

There is a strong relation between exposure and the number of accidents. Figure 3 shows the exposure rate, and the number of bicyclist fatalities per million inhabitants for 13 European countries and the United States. It demonstrates that a region with a high level of cycling is likely to suffer more bicycle fatalities than a region with low level of cycling, everything else being equal. Even though this analysis is simplified, it demonstrates how increased exposure correlates with a higher number of fatalities. A country with high level of cycling is also likely to have a high proportion of bicycle accidents of all road accidents (Schepers et al., 2014b). This also means that a region with few bicycle fatalities does not automatically mean that it is safe to cycle there, it is possible that the explanation is simply that few cycles. Similarly, a country with more than 30 fatalities is not necessarily worse than Sweden, where it is possible that there is greater exposure due to either larger modal share of cyclists or greater population.

Risk

The risk dimension describes the probability of being involved in an accident per unit of exposure, that is, the individual risk of being involved in an accident. Several factors influence the risk, for example, the design of the infrastructure, the composition of the road user, weather conditions, modal share, traffic behavior. If we multiply the exposure and risk, we get the number of accidents that do occur. This implies that we can either reduce the number of accidents by reducing the risk, by moving trips between different travel modes or to shorten the distance travelled.

If we look at the risk of bicyclists, this is a somewhat accident-prone travel mode. Blaizot et al. (2013) showed the injury rate for cyclists per million hours to be eight times that of the injury rate for car occupants, and the rate of serious injuries were even higher. This elevated risk of cyclists has been shown in several other studies of accident statistics (Bjørnskau, 2015; Tin Tin et al., 2010).

Figure 4 is a simplified description of the risk dimension on the national level (focused on fatality rates). It shows comparison of number of bicycle fatalities per inhabitant against the bicycle exposure per inhabitant (there are considerable uncertainties regarding

Figure 3 Comparison of bicycle exposure and the rate of killed bicyclists per million inhabitants. Source: Data: Santacreu (2018) and Castro et al. (2018), translated from Kröyer (2019b).

Figure 4 Comparison of the risk of fatal accidents and the rate of exposure for bicyclists. Source: Data: Santacreu (2018) and Castro et al. (2018), translated from Kröyer (2019b).

exposure of cyclists, and this way of presenting data can create a visual mathematical artifact (Brindle, 1994). This should therefore be taken with some reservations). We see that the number of fatalities per unit of exposure is considerably lower in the Netherlands, Denmark, and Germany compared to for example the USA. According to those numbers to cycle a given distance in the Netherlands is safer than cycling that same distance in the United States, given everything else being equal. It is also interesting that some of the countries that appeared to have relatively bad results when we simply focused on the number of fatalities (Netherlands, Denmark, and Germany), show relatively good results. We also see an apparent relation where higher exposure is related to lower risk. The fact is that the risk is not independent of the exposure (Elvik and Goel, 2019). This is often referred to as *safety in numbers*.

As those two simplified graphs, Figs. 3 and 4, demonstrates, the raw number of cyclist casualties misses important aspects of the situation. That there are 30 fatalities in Sweden per year is a fact, however, the raw number cannot tell us the general state of safety for cyclist, for that we need to consider both exposure and risk.

Safety in Numbers

Studies have shown that the accident rate at locations where there are many road users of a given type is usually lower than the accident rate at locations where there are few road users (Elvik and Goel, 2019), this is often referred to as *safety in numbers*. This

Figure 5 Number of collisions between motor vehicles and bicyclists at intersections based on number of road users. Source: Figure from Kröyer (2015b).

relation is often represented by the mathematical model shown in equation 1. N is the number of accidents, β_i are constants and E_i is the exposure of different road users.

$$N = e^{\beta_0} \prod E_i^{\beta_i} \quad (1)$$

If the constants β_i are equal to 1, that would mean that the accident rate per unit of exposure is constant, that is, simplified, a location with 10% higher exposure has 10% higher number of accidents. However, numerous studies have shown the constant (β_i) to be considerably lower than one, both for the volume of bicyclists and motor vehicles (e.g., Elvik and Goel, 2019; Kröyer, 2019b), usually in the range of 0.2–0.9 (Kröyer, 2019b). This applies to single bicycle accidents (Schepers, 2014) and collisions between bicyclists and motor vehicles (Kröyer, 2019b). There are two points we would like to stress: (1) despite that the risk per cyclists apparently is lower where the exposure is higher, the models suggest that the number of accidents is higher if the exposure is higher. (2) The exposure of motor vehicles influences the number of collisions. More bicyclists result in more accidents, and more cars results in more accidents, see Fig. 5. This means that by reducing the exposure of motor traffic we can reduce the number of collisions.

This can, with some simplification be interpreted that where there is greater volume of cyclists, each cyclist is safer. There are several theories as to why this relation exists. The most common ones are that this is due to:

1. Behavioral adaptation: more cyclists results in that those on motor vehicles are more aware of cyclists and hence adjust their behavior, resulting in fewer accidents (Brüde and Larsson, 1993).
2. More cyclists will correlate with a better infrastructure and/or maintenance for bicyclists, that is, societies that have many cyclists are perhaps more likely to have a more developed bicycle infrastructure.
3. The individual and collective experience of the road users. More cyclists will result in increased general knowledge in cycling and higher skills (Elvik, 2015; Johnson et al., 2014).
4. Numbers in safety, that is, that cyclists to greater degree choose their route from the safety of the route, or that this is partly a statistical artifact without any real relation (Bhatia and Wier, 2011; Brindle, 1994).

There is limited research regarding what is the “real” cause of the safety in numbers effect. If it is a causal effect or simply a correlation. Should the explanation be 1 or 3, then we can expect that the measure of increasing the number of cyclists would have positive effect on the safety of each cyclist. Should the explanation be 2 or 4, then the reason has no direct causal relation to the number of cyclists. Even though we cannot determine the contribution of each of those factors, there seems to be consensus that the effect, that the risk is lower if there are more cyclists, is at least partly true. We must however stress, that even if the effect would be fully causal, the model still indicate that more cyclists will increase the number of bicycle accidents. Also, there is no data available to determine if this will also apply to new micromobility devices. Practitioners should not rely on this effect “solving” the bicycle safety problem for them, but aim to improve the safety. For further reading, we refer to Bhatia and Wier (2011) or Kröyer (2015b).

Consequence

The third dimension, consequence, is how likely a road user is to be seriously or fatally injured if involved in an accident. This means that if we multiply exposure, risk (which gives the number of accidents) with the consequences we get the number of casualties. If we by some measure reduce the risk of fatality if in an accident by half, that would give the same effect on the number of fatalities as reducing the risk of all accidents occurring by a half, everything else being equal.

The consequence (the risk of injuries) varies with accident type, the crash mechanics, properties of the individual and the vehicle, the use of safety equipment, and the speed to mention a few. This dimension is “easily” influenced by those factors. Bicyclists are vulnerable road users, they can maintain considerable high speed, they interact frequently with motor traffic and have limited safety equipment compared to the occupants of cars. In the accident section, several factors that influence the consequence dimension were discussed.

Practical Implications

Cyclists are a complex group regarding traffic safety. Cyclists have relatively high risk of accidents compared to others and are among the most fragile road user groups. They are mixed with both car traffic and pedestrians, can maintain considerable speed, while they have limited safety equipment. To add to the problem, this is a highly heterogeneous group and there is considerable difference among the vehicles (cycles).

Accident statistics show that the two most common bicycle related accident types are single accidents and collisions with motor vehicles. Those two accident types also stand for the majority of reported serious and fatal injuries and thereby results in great health loss for the society. It is therefore important to both prevent those accidents and to mitigate the consequences of them. Collisions with motor vehicles are usually the greatest cause for fatalities, why our measures to improve bicycle safety must include influencing the motor traffic to reduce the threat they cause for cyclists, including reducing the impact speed in collisions and make them more bicycle “friendly”. We like to stress that even though other bicycle related accidents are not as frequent, they are also important. Also, there is usually considerable underreporting of bicycle accidents not involving motor vehicles, and in some countries they are not reported at all, hence, our accident statistics give us a biased picture of the situation, where we might underestimate the importance of those other bicycle related accidents. The accidents are also highly related to the exposure, including which groups cycles and where they cycle, why it is important practitioners study the local accident statistics.

System Perspective and the Individual Safety

There is a relation between exposure, risk, and the number of accidents. According to accident models, more cyclists and/or more cars combined and separately is likely to increase the number of collisions with bicyclists, and vice versa (Jonsson, 2005; Kröyer, 2016b). However, the total traffic safety effect is dependent on where those new cyclists come from. If the increase is due to that those cyclists are new road users (e.g., population is increasing), then this is an addition to the accident problem. However, if those new cyclists previously used motor vehicles, then the change would on one hand increase the risk of bicycle accident due to more cyclists, while reducing the risk of collisions with motor vehicles by reducing the number of motor vehicles (as well as fewer motor vehicles will reduce other accidents related to motor vehicles). Since collisions with motor vehicles are a great threat for bicyclists, then it is positive to have fewer cars.

According to the phenomenon safety in numbers, there are relatively fewer bicycle accidents were many cycles, that is, the risk of each cyclist is lower if there are many cyclists. The models also suggest that more cyclists will increase the number of bicycle accidents. However, theoretical calculations have demonstrated that transferring trips from motor vehicles towards walking or cycling may under certain conditions lead to fewer accidents (Elvik, 2009). A more thorough analysis from Schepers and Heinen (2013) demonstrated by estimation that in the Netherlands to increase the exposure of cycling by moving short trips from cars to cycling is likely to result in unchanged number of fatal accidents, however, increased number of serious injury accidents. This was due to reduced exposure of motor traffic, safety in numbers effect, and that cyclists can in urban settings take shorter and more direct routes than the motor vehicles, that is, to counteract the elevated risk per traveled kilometer, the number of kilometers (exposure) is reduced. It should also be added that to increase the number of cyclists does not mean that the number of fatalities will rise no matter what. We can influence that and prevent this increase. In the Netherlands, the cycling has increased by 40% since 1975, while yearly number of fatalities has been reduced (Schepers et al., 2017), similar results can be seen from Norway between 1983 and 2005 (Erke and Elvik, 2007).

There is also the question of individual perspective. Again, more cycling correlates with lower risk for each individual cyclist, all other things being equal. If we, for the sake of the argument, assume that the safety in numbers effect is in fact causal, then to reduce the exposure of bicyclists would increase the risk for each cyclist. For each cyclist it is not positive to reduce the number of bicycle accidents if it means that this individual will have greater risk than before of being involved in an accident. In that case, we would perhaps get an improved system safety with fewer bicycle related accidents, while simultaneously worsen the individual safety. If this is so, then one of the groups who would get worse individual safety are children, which will continue to cycle and rely on cycling for independent mobility.

Relation to the Use of Bicycle Helmets

Bicycle helmets have been shown to have considerable effect on the risk of serious head injuries, which is highly important given how frequent head injuries are in serious and fatal bicycle accidents. Just as with car occupants, where injuries from accidents are mitigated by use of seat belts, we can benefit from increased use of bicycle helmets.

There is sometimes concern that to discuss cyclists’ casualties and the real effect of bicycle helmet, or to encourage the use of helmet might be counterproductive. This due to concerns that (1) this would draw focus from improving the infrastructure for

cyclists, (2) it might lead to behavioral adaptations, where the cyclists would behave in more dangerous manners, (3) this might prevent people from cycling and thereby hinder the safety-in-number effect, or (4) lead to that those use motor vehicles instead which causes threat to other vulnerable road users.

Generally, we should give the road users our best available knowledge. Should the cyclist perceive it as unsafe to cycle, we should focus on improving the objective and subjective safety rather than to diminish that concern by over or understating the risks and effects of safety equipment. Also, to encourage road users to use helmets does not come instead of improving the safety through other measures, since the helmet will not save all and has no effect on serious non-head-injuries. A literature study by [Oliver et al. \(2018\)](#) showed that most of the literature does not support the theory of cyclist using helmets showing riskier behavior than those who do not. This study ([Oliver et al., 2018](#)) also looked at the relation between bicycle helmet legislation and bicycle exposure. Results from two studies possibly supported that the helmet law reduced cycling exposure, while 13 studies did not support it. 8 Studies had mixed results. There are methodological challenges studying this relation since several other confounding factors might influence changes in bicycle exposure. However, currently, the literature study does not support voiced concern that helmets might result in extensive reduced cycling exposure.

The Health Loss Paradox

Our traffic safety efforts are to prevent health loss in the society. Given the relative high risk of cycle accidents, lost years, and life quality, we must try to prevent those accidents or mitigate the consequences of them. However, we need to be aware of that there is a considerable positive health effect of cycling, which is considered to be even greater than the loss of health due to cycling accidents ([De Hartog et al., 2010](#)), even the use of e-bikes has been shown to increase the physical activity if it comes instead of using a car or public transportations ([Castro et al., 2019](#)) which is positive for health (we still do not know the health effect of other micromobility devices). From a health perspective, we must be careful not to reduce the health loss due to traffic accidents by perhaps causing an even greater health loss through public health, as well as limit the “safe” mobility of children that often rely on cycling for independent travel. We must therefore be aware that reduced cycling may cause counterproductive health effects for society. This supports the claim that we should aim at improving the objective safety so that we can achieve this increased public health while simultaneously minimizing the negative health effect due to traffic accidents.

Introduction: The Value of Cycling as a Boost to Urban Mobility

The large increase in private car motorization rates in developed countries has in many aspects contributed to significantly raising inhabitants' quality of life. But mass motorization has also generated negative externalities, such as energy dependence, traffic congestion, air pollution and noise, accidents, obesity, a sedentary lifestyle, and even social inequality challenge. These side effects underline the need to develop more sustainable and healthier transport modes. In the framework of the global environmental sustainability model currently in force, especially in urban areas in Western countries, the individual and social benefits of nonmotorized transport modes such as cycling and walking (including pedestrianization of large areas) have resulted in a revolution in the field of transportation, changing lifestyles, mobility patterns, and even the physical appearance of cities.

More specifically, the advantages of the bicycle as a synonym for health, energy savings, and efficiency are broadly confirmed by growing worldwide scientific research. In recent years, governments and public health agencies have made remarkable efforts to promote cycling not just as a leisure pursuit or sport but also for transportation as a remedy, due to its social returns: from the point of view of urban transport, the bicycle represents an opportunity to reclaim public space and create a flexible transport choice that enables easy access to denser urban areas such as city centers (Pucher et al., 2010). This mitigates the consequences of car use; from an economic perspective, cycling is often the least expensive mode and the most accessible for citizens as it minimizes public and private mobility costs, not only by fuel savings but also because it is a commuting mode that is exempt from taxation and does not require any insurance or a driver's license and has low vehicle and roadway maintenance costs. From the point of view of public health, cycling helps people lead physically active lives and counteracts major mortality risks such as a sedentary lifestyle leading to obesity. Lastly, in environmental terms, it is the most friendly and energy efficient of all transport modes, and even compared to walking.

A series of structural measures to promote the use of bicycles can be highlighted among the most common traditionally used public initiatives, including its integration into urban planning with the construction of cycle tracks and paths and the creation of bicycle parking areas; the promotion of the combined use or intermodality of the bicycle and public transport modes such as the bus and the train; the adaptation of traffic rules and road safety signs; and specific actions for the creation of facilities for cyclists, such as changing rooms and showers at their destination.

In this context, bicycle-sharing systems (BSS) have sprung up around the world during recent decades as an innovative mode of transportation for short trips. They coexist alongside traditional bicycle ownership (which may be more appropriate for longer distances) (Castillo-Manzano et al., 2016) and other road actors such as cars, motorcycles, goods vehicles, pedestrians, electric scooters, and so on, resulting in a complex urban mobility system. As cycling volumes are seen to be higher where BSS has been introduced, this study addresses the relevant issues of urban BSS user safety risks compared to cyclists using their own private bicycles.

BSS as a Public Tool to Encourage Cycling: What is the Relationship With the Private Bicycle?

Public BSS implementation has grown rapidly in many large cities around the world due to its potential to encourage cycling and so afford the benefits of active transportation and increased accessibility to multiple urban locations. In short, these systems enable users to share the use of a fleet of bicycles (through free loan systems or bicycle rental): a bicycle can be borrowed from a bicycle rack—a so-called “dock”—and returned to another dock in the same system, although some dockless systems also exist (Deighton-Smith, 2018).

Although this concept of the public bicycle has become remarkably popular in recent years, especially in certain countries in Europe, such as France and Spain, for example, it actually originated much earlier in Northern European countries with an already-established cycling culture (particularly in the Netherlands and Denmark) in the wake of Amsterdam's 1965 so-called “White Bike Plan,” which was free to users. Most of the White Bike Plan bicycles were stolen, however. Nonetheless, many years later, in 1995, a

second-generation project emerged in Copenhagen as a new public bicycle program called “Bycyklen,” with shared bicycles and a coin deposit system. The coin, worth roughly US \$1 was regained if the bicycle was placed in a dock, so this was still a free system where the bike could be kept for an unlimited time but legally not be brought outside Copenhagen, be locked to other places than a dock or taken off the street. The bicycles were, at least partially, financed and maintained through advertising plaques on the bicycles. According to the literature, relevant technological improvements were subsequently introduced during the last part of the 20th and the first part of the 21st centuries. As a result, the third generation of shared bicycles involving the use of magnetic smart cards, telecommunication systems, electronically locking racks, and mobile phone access was developed at Portsmouth University (United Kingdom) in 1996. This was followed by “LE Vêlo STAR” in Rennes (France) in 1998, “Bicing” in Barcelona and “Sevici” in Seville (Spain) in 2007, “Cycle Hire” in London (United Kingdom) in 2010, and “Citibike” in New York (United States) in 2014 to mention just a few of the systems. Apart from these automatic systems, the recent fourth generation of shared bicycles has drawn on existing experience to design an intelligent system to increase efficiency and usage. Based on smart bikes, it offers the addition of electric pedal assistance (namely, *e-bikes*) and access from mobile apps (e.g., *AirDonkey*, *Spinlister*, and *CycleSwap* in the Netherlands; *Call a Bike* in Germany; and *SoBi Hamilton* in Canada). In this case, the bicycles are connected to an integrated traffic management system and real-time information is provided by intelligent transportation technology. There are even solar-powered docking stations. In the current era of Big Data, the next challenge is currently being developed in the form of the fifth generation of BSS, with dockless bicycles provided by pioneer companies such as *Ofo* and *Mobike* in the Chinese cities of Beijing and Hangzhou since 2015, and in the Polish cities of Krakow (*Wavelo*, 2016) and Warsaw (*Acro-bike*, 2017).

As a result, BSS is one of the fastest growing modes of urban transport and data show that they are now ubiquitous on all continents. The number of cities with BSS has grown from just a small number in the late 1990s to more than 1000 cities around the world with BSS programs today and a joint fleet of over 4.5 million bicycles. BSS were adopted outside Europe for the first time in 2008 and some interesting websites, such as <http://bikes.oobrien.com/#zoom=3&lon=-60&lat=25>, currently provide a fascinating overview of BSS today, with online maps that show the location of docking stations in the main cities all around the world. For instance, at the current time, the eight leading cities in the top 100 for bicycle fleets are all in China. Next comes New York City in ninth position, followed by London, the highest-ranked European city.

Although the recent literature highlights the many benefits of BSS, some case studies analyzed in Europe and North America commonly show low BSS usage rates due to intrinsic flaws in BSS implementation that may act as deterrents for cycle users in general, thus reducing the efficiency of the public investment (or private investment in several places where there are BSS managed by private operators, for example, office campuses belonging to companies such as Google, Samsung, and Facebook in some US states, and Hong Kong, since 2017). These include, for example, congestion at peak hours, the inappropriate location of stations for intermodality, nonflexible schedules, slow loans and returns, problems with bicycle fleet redistribution from full to empty stations, low quality of service due to the lack of comfort and poor state of repair of the bicycle fleet, noncompetitive rental prices, damage due to vandalism, and so on.

In addition, public agencies and municipalities, mainly in European Mediterranean countries, often use bicycle share schemes to counteract the drawbacks of public means of transport and even as a policy to promote their city and develop local pride. Meanwhile, residents are obliged to subsidize the services by ceding public land or allowing advertising in a context of public budget austerity, which forces spending efficiency to be maximized. It is clear, therefore, that for the model to survive in the medium and long term, other complementary strategies should be promoted such as the transfer of users to bicycle ownership. According to successful experiences in specific cities such as Melbourne, Seattle, Buenos Aires, and London, a public–private partnership framework should be set up to exploit the infrastructure network created by public initiative and actions undertaken to boost the transfer to private bicycles. These would include, for example, the construction of safe public parking at places of origin/destination to allay the fear of theft, along with other facilities in large companies and public institutions (changing rooms, showers, etc.); the improvement of intermodality with other modes of urban transportation and “point-to-point” connections; and economic incentives for the purchase of bicycles that take into account the profile of new cyclists (i.e., cyclists of both sexes, not only young people with different income levels who make daily commutes and do not ride only for leisure, sport, recreation, or pleasure, but also for shopping, to travel to their place of work or study, and are committed to a healthy lifestyle).

One example of such incentives can be found in the Spanish region of Andalusia, where subsidies are provided to cofinance bicycle parking and storage areas in buildings.

To summarize, BSS and private bicycles should not be regarded as competing systems but rather as complementary ones that can be used to maximize the efficiency of public strategies and achieve a real modal shift to a more sustainable and healthy urban transportation system (Castillo-Manzano et al., 2015).

Other Health Impacts of Cycling: Comparison of Safety Outcomes of BSS and Private Bicycles

The scientific literature has consistently shown that the health benefits of cycling far outweigh the risks (Wegman et al., 2012). Nonetheless, for cycling to become accepted by more people, it is important that possible negative health effects derived from traffic accidents and hazards in urban settings are acceptable and the first step toward knowing if that is the case is to quantify the risks. It must also be taken into account that, with or without bicycles, road safety should be analyzed from different angles depending on whether urban or rural roads are being studied. The safety impact of cycling has been widely investigated in different parts of the world and has revealed the key role played by certain factors in collisions, including road geometry design, and cyclists’ decisions

regarding speed, route choice, and compliance with basic traffic safety laws. Nevertheless, a comprehensive risk comparison between BSS users and private bicycle riders is not often explored, although all experts seem to agree that the main causes of accidents are similar for both systems, that is, mainly deficient infrastructure when bicycle-only accidents are considered and risky behavior (distraction, alcohol consumption, excessive speed, etc.) for accidents involving vehicles and bicycles.

Moreover, according to certain studies carried out in the Netherlands, the inclusion of e-bikes in the urban mobility system may generate a feeling of greater safety compared to both shared and private bicycles (Schepers et al., 2014). A reason for this is that normal e-bikes in the Netherlands have a maximum speed of 25 km/h (15.5 mph). That is also the case in Sweden and most other European countries (unless the operator has a driver's license and a registered electric motorcycle or moped with insurance, etc.). If the operator tries to go faster, for example, downhill, the hybrid charger will kick in and maximize the speed to 25 km/h, whereas a traditional bicycle easily can reach speeds of 50 km/h or higher in steep downhill. This is in contrast to other countries such as China where, despite a decrease in the number of traffic fatalities from bicycle accidents, the number of e-bike accidents involving traffic casualties has increased. As of now, there were no upper speed limit for e-bikes in China but the government is planning to introduce legislation to require operators to have motorcycle licenses unless the e-bike is maximized to 30 km/h (18.6 mph). In the United States, e-bikes for unlicensed operators are maximized at 20 mph (32 km/h). Be that as it may, e-bike traffic regulation focuses on safety concerns (mandatory helmet use, maximum speed limit, etc.) and differs from one country to another. However, some BSS systems, for example, in Germany, already have e-bikes as an option to pedal bicycles.

Why do Public BSS Bicycles (Often Ridden by Inexperienced Cyclists) Seem so Much Safer Than Private Bicycles?

As has been stated previously, the recent rise of BSS has had a significant impact on urban transportation in many countries and cities worldwide. From a safety perspective, cycling with shared bicycles could present a priori some inherent characteristics basically related to the bike sharer's profile that perhaps seems to make it a more dangerous transportation mode than private bicycles: inexperienced and casual cyclists (on more than one occasion, tourists who are not sufficiently familiar with the urban environment and traffic rules) who use public BSS for short trips frequently combined with lower helmet usage (Fishman and Schepers, 2016).

Notwithstanding the earlier, relevant evidence has been found in the United States and Canada, for example, that points to lower urban accident and casualty rates for BSS than for privately owned bicycles, which could be supported by the so-called "safety-in-numbers" (SIN) effect. According to this theory, a reduction in the number of urban traffic accidents associated with the addition of BSS bicycles may be explained by a rise in driver and noncyclist (motorcycle riders, pedestrians, etc.) awareness, with these adapting their behavior, paying greater attention, and being more alert to bike share users.

Experts from international institutions such as the European Cycling Federation and the OECD go further and highlight other possible groups of factors that may explain differences in traffic accident and fatality rates between public shared bicycle and private bicycle riders.

1. Bicycle design, location, and infrastructure issues

Logically, a bicycle is a more fragile and risky vehicle than an automobile for traveling in cities but the BSS fleet is generally designed for slower and more stable riding than traditional bicycles, at least if we exclude northern Europe where most bicycles are sturdy and have upright riding styles. So compared to private bicycles in North America and southern Europe and many other places, BSS units are larger and heavier, which may mitigate dangerous or aggressive riding, while wider tires can better withstand pavement defects and powerful reflectors and bright colors improve visibility.

Regarding infrastructure, most BSS stations and racks are located in dense urban cores and in areas of traffic congestion, hence automobile speeds as well as bicycle speeds are lower and so, if an accident should occur, the consequences are, foreseeably, less severe.

2. Cycling experience

Mixed findings can be found for this point. On the one hand, some studies have revealed BSS users to frequently take greater care and ride more safely. They are more defensive in their riding due to their, on average, lower level of cycling experience. In this respect, while age and gender do not appear to be conclusive, it seems that there is a range of sociodemographic factors that indicate that private bicycle cyclists have greater cycling experience: they are people who see the bicycle as part of their healthy lifestyles, who demonstrate a greater stated willingness to purchase a bicycle, who have a higher level of education, who are ideologically more progressive, and who are city residents. BSS users are also on average younger, but typically not children, and children and older riders have higher crash rates than people in their 20s to 50s. For example, close to half of all bicyclists killed in accidents in Sweden are over age 65. And, the bicycle per capita fatality rate for people over 65 in Sweden is around 13 per million people for men and 3.5 for women, whereas the fatality rate for people aged 15–44 is around 1.5 for men and 0.8 for women. For people aged 45–64, the fatality rate for men is around 5.0 and for women around 2.5 per million people in that age group. So, if BSS systems are used mostly by people aged 15–44, we should expect lower fatality rates than for private bicycles.

On the other hand, other researchers suggest that less experienced BSS cyclists with lower levels of knowledge may be involved in a greater number of traffic accidents, which might neutralize their more cautious cycling behavior.

3. Cyclist behavior: speeding and helmet usage

It is well known that helmet usage plays a key role in the prevention of injuries and fatal consequences for riders in traffic accidents involving bicycles. This could support the implementation of helmet laws, despite the controversy that it creates among cyclists and cycling associations, which is reflected in the low rates of helmet use in most countries.

This is fully corroborated for public shared bicycles, with a majority of users reluctant to wear helmets compared to private cyclists. Among causes that could explain this can be highlighted the profile of occasional BSS users who mainly use shared bicycles for short trips; they, therefore, rarely possess their own helmets. Or, even if they own helmets they did not bring them along. The provision and maintenance of public helmets by a BSS does not seem to be the solution either, due to the risk of theft and hygiene issues.

In spite of private bicycle riders usually being more likely to wear a helmet and lower helmet usage rates being found among BSS cyclists, certain observational studies carried out in US cities do not conclude any significant differences between serious accidents concerning public BSS users and private cyclists. Notwithstanding, the promotion of helmet use through information campaigns and road safety education would be advisable, rather than by a mandatory law that could discourage BSS utilization and urban cycling in general (Woodcock et al., 2014).

Another safety issue related to cyclist behavior is cycling speed as, in general terms, greater cycling speeds may be associated with more severe traffic accidents. Empirical evidence for European cities such as Lyon shows that cycling speeds for BSS users are substantially lower than for private bicycle riders, probably due to differences in the design of the bicycles, as stated earlier.

Does “Safety-in-Numbers” (SIN) Theory Really Work?

Many authors agree that SIN is a valid argument for explaining how urban safety improves with increased numbers of cyclists (especially BSS users, who can develop a “network effect” by spreading the cyclist culture) and pedestrians on the roads, as a result of drivers’ and motorcycle riders’ greater awareness and caution shown toward cyclists and pedestrians (Elvik and Bjørnskau, 2017).

This effect might even be strengthened by, for example, public transportation agencies or municipal governments using a shared bicycle program in conjunction with other strategies, such as the provision of bicycle tracks or lanes or other facilities as tools to encourage a modal shift in urban transportation (Marqués and Hernández-Herrador, 2017), as in the case of the Spanish city of Seville (Andalusia) (Brey et al., 2017). As a result, other road users become more tolerant and regard cyclists as just another agent integrated into urban mobility rather than as a threat.

Notwithstanding, empirical data to date do not allow confirmation of the causal effect described by SIN theory, but simply point to a statistical correlation between urban traffic accident rates and the number of BSS users that suggests an opposite relationship, that is, there are large numbers of cyclists because cycling is a safer transportation mode for daily urban commutes, especially in European countries with a history of cycling such as Denmark and the Netherlands, where there is a high density of cycling facilities. In neighboring Sweden, cycling has seen a renaissance in the last few decades, especially in the larger cities. In spite of more cycling than in the 1980s, the number of fatalities involving bicyclists has decreased from around 75 per year in the late 1980s to around 20 per year in recent years. Not just SIN explain this but also lots of new bicycling facilities and separation of bicyclist from motor vehicles. Still, around 70% of Swedish bicycle accident fatalities involve motor vehicles even though only about 10% of bicycle injuries that require medical care involve motor vehicles.

Conclusions and Policy Recommendations

Considering all of the earlier, it is concluded that BSS are linked to lower accident rates than private bicycles, so implementing a shared bicycle scheme could be associated with improved urban road safety. However, there is no simple and obvious explanation for this fact. In addition to the well-known SIN effect, the specific characteristics of public shared bicycles as well as who rides them may contribute to lower accident risk (lower riding speed, greater visibility, physical design, fewer riders above age 65, etc.)

Whatever the case, this statement should take into account the fact that some limitations on analysis may skew the comparison between shared and private bicycles. For example, safety data for BSS usually come from operators (who might be underreporting outcomes), while for personal bicycles they come from police reports. BSS injury crashes are obviously also reportable by the police but the report may not show if the bicycle was privately owned or of BSS type. Furthermore, bicycle trips made using a BSS are generally shorter (among other reasons, to avoid additional fees), which leads to a lower per-trip risk rate compared to private bicycle riding. On the other hand, when local governments implement a BSS in conjunction with other strategies to encourage urban cycling (facilities, specific infrastructure, etc.), not only the safety of BSS users is expected to improve, but that of all people who choose to cycle, whether by shared or private bicycle.

This positive effect could be enhanced by the application of certain recommendations, such as the introduction of segregated bicycle tracks to prevent cyclists moving into car traffic and accidents with pedestrians (such as in Scandinavia and the Netherlands) and elimination of bicycle lanes as used in the United States and some European countries; a more consistent methodology to report accident data that separates BSS and private bicycles; and the incorporation of safety intelligent technologies into both shared and private bicycles.

And all this considering that, nowadays, there is a new urban mobility paradigm that threatens even the most organized cities, in which sustainability and efficiency present challenges in terms of new actors that share the same public space (electric scooters, hoverboards, etc.) and new conflicts that suggest more significant safety concerns requiring new regulation.

Introduction

This article is focused on safety issues for road users traveling on or under bridges. Its emphasis is on motor vehicle, bicycle, and pedestrian traffic but it also touches on safety issues related to rail and seafaring vessels. Most of what is presented is based on the author's own research and has a focus on the United States. However, what is presented in the first couple of sections, describing structural failures leading to vehicle occupant deaths, is taken from the literature, with references presented at the end of the article as further readings.

A bridge safety issue of almost similar magnitude, as traffic safety on bridges is suicides, committed by people jumping off bridges. Suicides will not be further discussed in this article since it is not primarily a transportation issue, and in the case of jumping off bridges do not take other people's lives. However, it can be concluded that suicides seem to be concentrated to fairly few, monumental bridges, and that suicides at those locations can be prevented or even eliminated by installing fencing ([Pelletier, 2007](#)). Also, suicides related to transportation facilities are further discussed by Brendan Ryan in this Encyclopedia.

Another safety issue, which will not be discussed in detail in this article, is sabotage where terrorists blow up or threaten to blow up bridges, or use a bridge as a confined area where pedestrians cannot get away from motor vehicles targeting random pedestrians to affect fear in the general population. An infamous case of this issue occurred in London, England, in 2017 when an attacker drove a car into pedestrians on the sidewalk along the south side of Westminster Bridge, injuring more than 50 people, four of them fatally. Similar events have occurred in, for example, Stockholm, Sweden; Nice, France and New York City, but those incidents were away from bridges. This type of security issue could become more common in a future and bridges may be a good place to inflict maximum effect.

Structural Failures Leading to Vehicle Occupant Fatalities in the United States

When thinking of bridge safety, the general public may limit their thoughts to structural failures of bridges. And, there were over 500 failures of bridge structures in the United States alone in the 12-year period (1989–2000) according to a study by [Wardhana and Hadipriono \(2003\)](#). The age of the failed bridges ranged from 1 to 157 years, with an average age of 53 years. The most frequent causes of bridge failures were, according to this study, attributed to floods and collisions. In most of these cases, no people were killed but they all caused delays to travelers and costly repairs.

The deadliest bridge collapse in the United States in the last 60 years did not involve motor-vehicle traffic. It occurred in 1993, when a passenger train crossing the Big Bayou Canot Bridge in Alabama derailed. The locomotive slammed into a bridge span and initiated the structure's collapse bringing the train into the river, killing 47 people onboard ([Jenkins, 2017](#)).

The second deadliest bridge failure in the United States was the 1967 Silver Bridge collapse between Point Pleasant, W.V. and Gallipolis, Ohio. The aluminum suspension bridge collapsed, plunging 32 vehicles into the Ohio River, killing 46 people.

The third deadliest collapse was the 1989 Cypress Street Viaduct failure in Oakland, California. A 6.9 magnitude earthquake caused a number of structures to collapse—including a portion of the upper tier of Cypress Street Viaduct, a section of Interstate 880. And 42 of the quake's total 67 deaths occurred as a result of the viaduct's collapse.

The fourth deadliest collapse in the United States was the 1980 failure of the Sunshine Skyway over Tampa Bay in Florida. The bridge was struck by a ship during a thunderstorm causing the structure to collapse, sending six cars, a truck, and a Greyhound bus plummeting 45 m into Tampa Bay with a total of 35 people killed.

In more recent time, the I-35 westbound bridge over the Mississippi River in Minneapolis collapsed in August 2007 killing 13 people. The National Transportation Safety Board (NTSB) cited a design flaw as the likely cause of the collapse, noting that a too thin gusset plate ripped along a line of rivets, and high weight on the bridge at the time contributed to the catastrophic failure.

Even more recently, in March 2018, a pedestrian bridge under construction collapsed in Florida killing one construction worker and five people in cars at a traffic signal below.

Another bridge collapse that took six lives occurred in 1964 when a ship collided with the Lake Pontchartrain Causeway in Louisiana. And, there were 10 deaths in 1972 in Georgia also as a result of a ship striking the bridge. Another highly publicized bridge collapse occurred in 1983 when the Mianus Bridge on the Connecticut Turnpike in Greenwich, Connecticut collapsed after one of the pins used in its construction had been sheared, killing 3 people.

Adding up these nine deadly bridge collapses gives a total of 208 fatalities in the 60-year period (1958–2018). In other words, these crashes by themselves caused, on average, 3.5 fatalities per year. If we add all other known deadly bridge collapse deaths to these, another 68 occurred in the period 1959–2018. So, we get a total of 276 deaths, or, on average, 4.6 fatalities per year over the last 60 years caused by structural failures of bridges.

Nonfatal bridge failures can also have major consequences. The collapse of a bridge on Interstate 85 in Atlanta in March 2017 meant that 250,000 commuters who travel the highway daily had to find new routes to work and school.

Besides collapses of bridges, there are other structural failures that can lead to accidents and injuries. Examples of this include when rebar cover is lost or overlays debond. It is difficult to find data on crashes resulting from such events but the number of fatalities is most likely small compared to that of bridge collapses.

Structural Failures Outside the United States

Structural bridge failures obviously happen more or less everywhere in the world. And have happened since before motorized traffic was introduced. For example, a well-known bridge failure occurred in the year 312 when the Milvian Bridge in Rome collapsed during the Battle of the Milvian Bridge. A much more recent bridge failure, and one of the deadliest in recent years, also occurred in Italy. It happened in August 2018 when sections of the Ponte Morandi collapsed. This is a series of cable-stay bridges for the motorway between Genoa and Liguria. A total of 43 people died.

Worldwide, roughly 100 people (road users and train occupants) per year have died in the last 10 years as a result of bridge collapses. It is obviously difficult to get accurate data from all countries in the world, but if 100 deaths per year is a good estimate, then the annual fatality rate is around 0.013 fatalities per million people. This is very similar to the US fatality rate from bridge collapses, which would be around 0.014 fatalities per million people if we use the figure of 4.6 fatalities per year and current population. These rates can be compared to the United States and worldwide fatality rates for “traffic.” In 2017, the United States had just over 37,000 highway fatalities giving an annual fatality rate of around 115 per million people, and if we use the last 60 years, as above for the US bridge collapses, for “highway” fatalities, we get a rate of around 170 per million people. That means that there were more than 11,000 times as many people killed in traffic accidents as in bridge collapses, putting the safety problem of bridge collapses in a perspective that few people among the public would have guessed. Worldwide, in recent years, the World Health Organization estimates that 1.25 million people die in traffic accidents every year, giving a current annual fatality rate of 160 per million people. In other words, based on a macro analysis, structural safety of bridges, with respect to risk of death, is not in the same order of magnitude as traffic safety. But, can we thereby conclude that bridge safety is not a big concern? No, even if bridges do not collapse, they may be less safe from a traffic-safety viewpoint than other roadway segments because the geometric features of bridges differ from other roadway segments.

Accidents not Related to Structural Failures

It is hard to find information on crashes related to bridges that do not involve structural failures. A literature review in 2017 came up with a published bridge crash study by [Hurt et al. \(2009\)](#) in Kansas. Its findings include, “In 2005, there were 1,919 crashes on bridges in Kansas, including 26 fatal crashes. While overall these accounted for less than 3% of all traffic crashes, they accounted for almost 7% of the total number of fatal crashes.” And, that percentage seems to refer to crashes on bridges rather than under or near bridges.

Functional obsolescence or imperfect geometric design seldom directly cause crashes. But nonoptimal designs may increase the chance of a crash and aggravate injuries once a crash occurs. But it is almost always road user behavior that is the primary factor behind a crash. Therefore, an analysis of fatal bridge injuries, with an intent to reduce that number, should look at how driver and pedestrian behavior can be influenced with, for example, information technology. But certainly, behavior can also be influenced by changes to geometric design.

A substantial subset of fatal injuries on bridges is made up of pedestrians and bicyclists—road users that often have no realistic alternative to using a functionally deficient bridge when they cross a river or an Interstate highway, as illustrated in [Fig. 1](#). Here pedestrians have a choice between a 0.2-m shoulder or a 0.5-m center island when crossing I-95 in Bangor Maine, United States. However, there is certainly not much published literature in the area of pedestrian and bicycle safety of bridges. One study that touches on the subject of pedestrian safety is a Korean study by [Tay et al. \(2011\)](#), which concludes that fatal and serious pedestrian-vehicle crashes in South Korea were associated with collisions involving pedestrians who were on bridges. However, the study does

Figure 1 Bridges over highways often have no safe space for pedestrians and bicyclists.

not go into the influence of geometric features or other characteristics. With respect to bicyclist safety, a Belgian study by [Vandenbulcke et al. \(2014\)](#) can be mentioned. They investigated risk factors for bicyclists limited to infrastructure, traffic, and environmental characteristics. The results suggest that a high risk is statistically associated with the presence of bridges without cycling facilities, such as bike tracks.

American Society of Civil Engineers (ASCE) states in their Report Card for America's infrastructure that one in nine of the nation's bridges are rated as structurally deficient. The Federal Highway Administration (FHWA) estimates that to eliminate the nation's bridge deficiency backlog by 2028, the United States would need to invest \$20.5 billion annually, while only \$12.8 billion is being spent currently. These sums do not include the cost of fixing bridges that are not structurally deficient but unsafe in some other way.

A primary goal if finding that bridges are unsafe may not be to recommend how to redesign existing bridges but how to use ITS and other information technologies to inform (warn) road users of upcoming real-time safety issues. Such a system has been sketched and presented by researchers at the University of Montana ([Vazquez, 2014](#)). At a later development stage, ITS technologies can and should be used to take over control from drivers if they approach a bridge in an unsafe manner, such as at too high speed for conditions or when they are getting too close to pedestrians or bicyclists.

There is a wealth of literature on guardrail and bridge rail design, and crash test results of different designs. And, there is a study of motorcycle fatalities from 2003 to 2008 in the state of Indiana showing that a major correlate of death is bridge-guardrails ([Nunn, 2011](#)). A specific issue with bridge piers, besides being unforgiving, is that they often cut the vision field ahead. That has been identified as a crash contributor for bicyclists in particular ([Jordan and Leso, 2000](#)).

Another specific safety issues relates to passing under low-clearance bridges with commercial vehicles. An experiment using "old-fashioned" ITS technology for reducing such crashes in Maine was presented by [Belz and Garder \(2009\)](#).

A goal when designing bridges should be to reduce human suffering and death caused by unsafe behavior at or near bridges in combination with less-than-optimal geometric design of said bridges. It is very clear that many bridges—at least in the United States—lack sidewalks as well as wide shoulders and therefore cause a special threat to vulnerable road users, as discussed in connection to [Fig. 1](#). Safety is the focus of this article. However, badly designed bridges are frequently the Achilles heel in urban and suburban pedestrian and bicycle networks and certainly have mobility and accessibility implications too.

The analysis below excludes suicides and homicides and covers only transportation-related crashes.

Analysis of Fatal Bridge Crashes in the United States

When analyzing fatal crashes in the United States, the Fatal Analysis Reporting System (FARS) database is typically a reliable source, but only for crashes that involve motor vehicles in traffic on public roads and streets. This database is maintained by the National Highway Traffic Safety Administration (NHTSA) and covers all public roads in the United States, including bridges. However, FARS does not have a field (category) indicating whether a crash occurred on a bridge or not and it is therefore difficult to identify if a crash occurred on or under a bridge or somewhere away from the bridge without going through each individual crash and using GPS coordinates. And, to make things worse, entered GPS coordinates are often inaccurate. A different approach is needed.

Fatal crashes are typically written up in local newspapers and covered by television stations. But, information from the past is sometimes not archived in a way that makes it easy to retrieve. Therefore, only 2016 fatal crashes have been analyzed here. Newspapers and other media sources from all of the United States were searched on a daily basis throughout 2016 and then the search was continued through August 2017 to get updated information on crashes that occurred in 2016. The news articles frequently show photos or videos from the crash site making it possible to identify exactly where a crash happened. This combined with the write-up of the news story typically gives a good picture of what happened, though the information may at times be biased or false, if witnesses lie or reporters misunderstand what happened. There may also be fatal crashes that neither newspapers nor TV

stations find out about, but that would be rare. Rather, most fatal crashes in the United States are covered by multiple newspapers and multiple TV stations.

Google Satellite and Street View were used to get more detailed information about the geometry of the site of the crash.

Results

As earlier mentioned, looking at recent history, bridge failures kill almost five people per year in the United States, and that is not insignificant. But there are many more people killed in crashes on bridges, or going off bridges, or hitting abutments and piers on a road passing under a bridge.

Below are the results of an analysis of “all” fatal crashes on or under bridges in the United States in 2016 and a subset of nonfatal bridge accidents in Maine.

Fatalities on or Under the US Bridges in 2016

As earlier mentioned, fatal crashes on or under bridges were found through analysis of media publications in newspapers, television, etc. It was verified that the crash had not been deemed a suicide and that it physically occurred on or under the bridge/overpass. It can be concluded that the United States in 2016 had at least 258 fatal crashes that were not deemed to be suicides or planned homicides. These crashes killed 314 people on or under bridges. There were 244 car/truck occupants, 35 MC riders, 4 bicyclists, and 31 pedestrians killed. Out of the 31 pedestrians killed, at least 7 were pedestrianized motorists who had gotten out of their motor vehicles after their vehicle had stalled, been involved in a minor crash, or other event.

Overall, 81 of the fatal crashes happened under the bridges (colliding with piers, etc.) and 174 on top of bridges. In 84 of the 174 crashes on bridges, the bridge was traversing water and in the remaining 90 cases, the bridge was passing over another highway, railroad, or similar facility.

Of the 81 crashes under bridges, 65 were single-vehicle strikes of piers or abutments and one was a truck having a raised bed that struck the bridge. Two cases involved pedestrians being hit while walking through underpasses and one case was an MC rider having stopped to shelter from rain. In three cases, an occupant drowned when driving under a flooded underpass.

Of the 174 crashes on top of bridges, 84 were single-vehicle crashes. In 21 of them, the motorist was killed as a result of striking a bridge railing or guardrail without going off the bridge. Of the multi-vehicle crashes, 17 started out as rear-end crashes, 6 as sideswipe, and 27 as head-on crashes whereas 8 of them could not be determined based on media reports. Nineteen of the crashes on bridges involved a pedestrian or pedestrianized motorist. In eight of the 19, the pedestrian was struck and killed without falling off the bridge, in five cases the pedestrian was stuck and thrown down off the bridge, and in the remaining six cases the pedestrian also fell down but it is unclear how it happened except the incidence is not deemed to be a suicide. One fatality occurred as a result of a “pedestrian” climbing a bridge and then lost their balance and fell, so this is not a traffic accident but rather a climbing accident.

Out of the 174 fatal crashes on top of bridges, 89 had a vehicle or its occupants or other road-user being thrown down onto the highway or river below the bridge with 53 of them not being preceded by a multi-vehicle crash but rather were caused by a driver losing control and going through or over bridge railings, showing the need to strengthen and/or raising these. In most of these cases, it was the occupants of the vehicle who were killed but in one case, a motorist survived whereas four “pedestrians” were killed when the vehicle landed on top of them. In 14 crashes, there was a multi-vehicle (or multi-unit) crash preceding the going off of the bridge. Five of the crashes mentioned in the previous paragraph involved a pedestrianized motorist having exited their vehicle and being hit by a passing motorist before being thrown down, and in another two, a motorist got out of their car and, seemingly by mistake, fell down when they stepped over a low railing. These two could possibly have been suicides but were deemed by police as accidents.

The media reports point toward at least 21 of the crashes (8%) involving alcohol or drugs but this may be an underestimate. Ice or snow was a definite contributor in only eight of the cases. In other words, nationwide, better snow or ice removal or real-time information about bridge friction coefficients, would not greatly influence the total number of fatalities.

Structural failures prior to the “accident” did not contribute to any fatalities on the US bridges in 2016. Debris falling from a bridge as a result of a crash took one person’s life.

Two of the 2016 fatalities involved workers doing reconstruction of bridges. One of these was a traffic accident where one worker was killed in a 50-ft. fall after a (non-construction) driver of a truck hit the boom lift, which the worker was using. The other fatal accident was not a traffic accident but involved contractors painting a bridge. The person was standing on a platform tied to the bridge by a series of ropes and cables when one cable broke and the platform suddenly tilted, throwing five workers into the water, killing one of them.

Analysis of Nonfatal Bridge Crashes in the State of Maine

Analysis of nonfatal crashes is here limited to the state of Maine. Maine Department of Transportation provided crash data and AADT information to calculate exposure. However, exposure of pedestrian and bicycle flows were not gathered. The safety analysis covered not just locations where crashes had occurred. Crash-free locations, in particular bridges, were also included.

Maine Bridges

Maine has around 2515 bridges and overpasses that are longer than 20 ft. There are also 1374 bridges with short spans of 10–20 ft. As of 2016, the State of Maine owns and manages 2744 of these bridges. For the 3-year period (2011–13), there were 765 reported crashes on, under or very near bridges in Maine with 79% of them occurring on top of the bridges and 8% under the bridges and the remaining 13% just off the bridge, but still classified as bridge related. Overall, 28% involved personal injury, which is slightly lower than for crashes away from bridges. A significantly higher percentage of crashes occurred during ice and frost conditions on bridges (19.5%) than on other segments (5.1%). Adding snow to that, 30% of bridge crashes in Maine happened when the roadway was covered by snow or had icy conditions. So, even if snow and ice is not a nationwide issue with respect to fatalities, it seems to be a significant issue in Maine, and probably in other northern states, with respect to property-damage crashes.

A detailed analysis of crash rates was done for two of the 16 counties in Maine. The crash rate per hundred million vehicle miles (HMVM) traveled for all bridges was 317 for Aroostook County and 244 for Kennebec County. This can be compared to the average statewide crash rate of around 195 for the 3 years (2011–3). The injury crash rate, including possible injuries, was on bridges 52.9 per HMVM for Aroostook County and 58.8 per HMVM for Kennebec County. The average statewide injury crash rate for all public roads in Maine was around 59 per HMVM for these years. So there were more reported crashes than “expected” but just expected number of injuries, meaning that the average severity of the crashes is lower than for surrounding areas. Maybe crashing into bridge railings cause property damage but, on average, is “safer” than going off the road and hitting utility poles, trees, and other dangerous objects.

The above numbers are averages for all roadways in these counties, and bridges may be more common on some roadway categories than others. If we look at different roadway categories in these two counties, we can see that the average crash rate on Interstate bridges was almost exactly double that of all Interstate segments (130 vs. 64 per HMVM). For other principal arterials, the average crash rate on bridges was also double that of nonbridge segment (223 vs. 114). For major collector roads, bridges also have higher rates than other segments (240 vs. 154). The difference is even greater for local roads with bridges in these two counties having an average crash rate of 1230 versus the average rate of 247 for local roads in this 3-year period. These numbers indicate that we have crashes at and away from bridges, but that the bridges have roughly double the number of crashes compared to other segments on a per mile basis.

Discussion

There is a lack of knowledge of traffic safety issues of bridges. People, including safety experts, often focus on structural concerns rather than functional ones (ASCE, 2013). This article shows that mortality-wise, traffic safety is a problem roughly 60 times greater than structural issues. To focus only on the 1.5% of fatalities that are caused by structural failures will not optimize safety. Obviously, we should not relax structural standards or safety inspections, but we should complement them with bridge roadway safety audits.

Roughly one person dies every day in crashes on or under bridges in the United States. A majority of those killed are occupants of cars or trucks but MC riders and pedestrians are also often victims. About 32% of the fatal crashes occur under the bridge, with a majority being single-vehicle strikes of piers or abutments. In other words, better protection of piers and abutments should be a priority. Of the crashes on top of bridges, almost exactly half are single-vehicle crashes, typically striking guardrails and then sometimes tumbling down from the bridge. In just over half of the crashes that start out on top of bridges, the fatality is a result of a road-user being thrown down onto the river or highway below the bridge. Stronger and higher guardrails should immediately be installed on “all” bridges. Structural failures prior to the “accident” did not contribute to any fatalities on the US bridges in 2016, but the year is a bit of an outlier, and two of the fatalities involved workers doing reconstruction of bridges.

Within a few decades, we may have transitioned to highly automatic vehicles (HAVs) when it comes to purchase of new vehicles. However, non-HAVs will probably continue to travel across bridges for the foreseeable future, at least for several decades. And, even if non-HAVs eventually are prohibited in traffic, there will be pedestrians and bicyclists using urban bridges, so the safety of non-HAVs will still be important.

Biography

Per Erik Gärder is a professor of Civil Engineering at the University of Maine, United States, since 1992. He has a PhD from Lund University in Sweden and he was at the Royal Institute of Technology (KTH) in Stockholm, Sweden from 1983 to 1992. His research interest is focused on forecasting, designing, and evaluating facilities with emphasis on the traffic safety.

Carsharing Safety and Insurance

Introduction and Background

Insurance is a critical component of commercial activity in virtually every corner of the economy. It is a centuries-old industry that serves as a hedge against risk, the unknown, and the unpredictable costly events that can happen in daily life. Most people are familiar with the consumer-side of insurance products, including automotive, homeowner/rental, and life insurance policies. Some people also obtain insurance for more specialized risks, such as earthquakes or floods. Additionally, commercial entities from small businesses to corporations seek insurance to protect themselves against the liabilities that arise through the delivery of their product and services. Insurance for business can cover a broad spectrum of different risk types. The specifics of coverage depend on the nature of the business, as well as the potential costs that could be incurred through a realization of the risks it carries.

Carsharing (short-term access to a fleet of vehicles through a private company), as a transportation business, is no exception to the need for insurance. As a service that moves people, it must hedge against a variety of risk factors that can cause property damage, injury, or death. Furthermore, the shared mobility industry is predominantly comprised of private sector enterprises. Of course, many of these enterprises ultimately interface with the public sector, either in the form of curb space allocations or public transit integration. But in spite of these connections to the public right-of-way, the privatized nature of the industry has implications for insurance. This contrasts with other sectors of the surface transportation system, where insurance is either: (1) a cost born by the consumers or (2) irrelevant to vehicles not traditionally covered with insurance (e.g., bicycles) or vehicles run by public agencies (e.g., buses and trains). While public transit systems have risk management or may have supporting insurance policies, such policies and risk are generally implicitly backed by the public sector tax base. This is not a resource available to back catastrophic losses for systems that are almost fully privatized like carsharing. Modern carsharing emerged in North America during the mid-1990s with the establishment of carsharing in Montreal. A few years later, it was established in the United States, beginning in Portland, then Seattle and Boston, before spreading to multiple urban areas in the form of independent nonprofit and for-profit organizations. Because of its pioneering role, it faced a number of challenges in gaining acceptance with cities and consumers, both core to its survival. But beyond those business-related challenges, carsharing also faced major challenges with the insurance industry. The concept of carsharing in the United States was largely untested, and for an insurance industry accustomed to calculated risk and pricing that is supported by vast amounts of empirical data, the prospect of insuring it came with great risk, and thus commanded a significant premium.

At the center of insurance pricing are questions related to the safety risks of specific shared mobility services, including carsharing. These questions relate to the likelihood of injury to the user as well as injury to the general public from the service availability. Questions also relate to concerns associated with private and public property damage. This not only applies to the service assets but also to those of others (e.g., peer-to-peer carsharing in which individuals put their own vehicles into a shared fleet managed by a third-party provider), which could result in misuse or vandalism. Ultimately, questions regarding the level and costs of risk can be answered through experimentation and building empirical evidence with emerging services that depart from the traditional models. But, the early days of carsharing were fraught with challenges convincing insurance companies to cover such services. The absence of such coverage can prevent services from being able to operate and the withdrawal of such coverage can force existing operations to shut down. This latter circumstance was the experience of Buffalo CarShare in 2015, which served lower-income residents of the city, and was required to cease operations when its insurance coverage was withdrawn (Johnson, 2015). This withdrawal was the function of the lack of profits being made by the insurer and insurance laws within New York. Specifically, New York was (and still is) a "no-fault" state, meaning that insurers must cover any economic losses of the insured, including medical bills, forgone earnings, and other expenses resulting directly from an injury, regardless of who is at fault for the incident (New York State, 2020). The purpose of no-fault insurance (which is also known as personal injury protection) is to pay claims quickly. The intention of the law is to limit the time and expense of litigation that otherwise must occur to legally determine who is at fault and by what degree. Such determinations delay the compensation of those injured and lead to the associated stresses, while monetary bills from the costs of the incident accrue. Twelve states and Puerto Rico have laws requiring such insurance policies, all of which were enacted in the 1970s. Five additional states had such policies enacted during this period but later repealed them. While no-fault policies impose a

Figure 1 Shared mobility ecosystem.

guaranteed cost on the insurer for any incident, they are also designed to limit the amount of tort litigation that can occur ([Insurance Information Institute, 2020a,b](#)). The existence of these policies has its advantages and disadvantages, but in the specific case of Buffalo CarShare and its insurer, the no-fault requirements were determined to be an insurmountable disadvantage with an accident that was deemed to be *not* the fault of the carsharing driver ([Johnson, 2015](#)). The no-fault legislation increased the exposure of the insurers to a degree that was not acceptable to the industry, and Buffalo CarShare could not find another carrier. Other carsharing operations still do exist in New York state, including the non-profit Ithaca Carshare in upstate New York. Nevertheless, the carsharing landscape is increasingly dominated by larger actors.

The experience of Buffalo CarShare is illustrative of how insurance dynamics can make or break an organization, especially a smaller one within a new industry. It shows that insurance considerations, while generally among the more mundane aspects of business operations, are critically important for survival. Despite the setbacks and lessons learned, the carsharing industry served as an important pioneer for the rest of the shared mobility industry. The full scope of this industry is articulated in [Fig. 1](#), as presently consisting of micromobility, transportation network companies, taxis, microtransit, among others ([Shaheen et al., 2020](#)). As such, the shared mobility industry has evolved into new businesses and a variety of new modes, since carsharing services were first launched. In the sections that follow, the authors discuss insights from previous work as conducted in [Shaheen et al. \(2016\)](#) on carsharing safety and insurance.

Carsharing and Insurance

Previous research from [Shaheen et al. \(2016\)](#) titled: *Understanding Carsharing Risk and Insurance Claims in the United States* explored how insurance rates differed depending on the group that was covered and their crash risk. By analyzing data supplied from six different carsharing operators, conclusions can be drawn regarding carsharing risk. The data supplied included individual claims filed by the operators. The operators were all single city operators, and most operated under a nonprofit business model. The data spanned a total of 328,726 valid trips and contained 125 valid insurance claims. This amounted to 2630 trips per claim. The time span of data differed across operators, but in aggregate it spanned 2008-15 and constituted 28 operating years of data. It also comprised 733 insured vehicle years of data. In other words, each vehicle in the dataset was insured for some number of years (e.g., vehicle-years insured) and 733 is the sum of all those vehicle-years in the dataset. The total costs from claims within the dataset amounted to US \$578,801. The deductibles varied across the operators and policies and ranged from US\$0-10,000 per claim. However, most of the deductibles were on the low end of this range, with 45% of claims carrying a US\$1000 deductible, and 89% of deductibles amounting to US\$1000 or less. To standardize the computed costs to insurers across policies and operators, the cost of all claims re-calculated for this analysis assumed a deductible of US\$1000. Based on this assumption, the average cost per claim was US\$4630, and the median was US\$2189 per claim.

By comparing key risk metrics in carsharing with similar metrics of the broader automotive industry, the data can show the degree to which carsharing differed from the general population. Claim activity in the broader automobile insurance industry is profiled along with a myriad of attributes. A major curator of data in the insurance industry is the Insurance Institute for Highway Safety

(IIHS). The research institute collects and publishes data on automotive claims and additionally conducts its own crash safety tests for the industry (which are different from those of the National Highway Traffic Safety Administration (NHTSA)). The insurance industry measures the rate of claims in units of: "Claims per 100 Insured Vehicle Years." This is the number of claims that the industry receives for every 100 vehicles insured over a period of 365 days. On average, the insurance industry experienced 6.01 collision claims per every 100 vehicle years insured in 2015 (IIHS, 2020). Other types of claims were less frequent in terms of the units, including bodily injury (0.91), property damage (3.72), and comprehensive (2.72). For comparison, the claims in the carsharing dataset suggest that there were 17 claims per 100 insured vehicle-years. The higher claim frequency for carsharing vehicles is notable, but it is also logical for a few reasons. First, shared vehicles of any kind are used more intensively than personal vehicles and by a wider variety of individuals. Second, carsharing vehicles are typically used by demographics that have a higher risk profile within the general population. One example of this is age, where carsharing users are typically younger. As with traditional personal vehicle insurance, younger drivers are regularly categorized as higher risk due to inexperience and sometimes more reckless behavior. This dynamic is shown in broader industry data presented in [Fig. 2](#), which plots several key risk statistics by the age of the claimant. The figure is

Figure 2 National claim and cost data by age.

Figure 3 Number of carsharing claims by age.

derived from data assembled from IIHS for the 2002-04 model passenger cars (IIHS, 2007). The data show the relative change in claims per 100 insured vehicle years, costs per 100 insured vehicle years, and cost per claim for collision and property damage claims. Notable within the figure is the convex curve that is clearly present with claims per 100 insured vehicle-years and costs per 100 insured vehicle-years. These two measures find their minimums in the 60s age cohort and their maximums in the younger and older demographics. It is the younger demographic that is overrepresented within the carsharing population relative to the general population. For example, in a survey of North American carsharing operators, [Martin and Shaheen \(2011\)](#), found that just over 35% of respondents were younger than 30, while 31% of respondents were between the ages of 30 and 40. Hence, well over 60% of carsharing users fall within the younger cohort of drivers. These two factors (vehicle use intensity and user age) likely serve to drive up the claims per 100 vehicle years of carsharing fleet vehicles.

[Shaheen et al. \(2016\)](#) found a similar pattern in the data provided by carsharing operators, but the distribution was not as pronounced when adjusted for miles driven. But in aggregate claims, the pattern holds in that the majority of claims are filed by users who are mostly in their 20s. Different adjustments, depending on the denominator, suggest the correlation with user age is mostly due to a large number of users within the age cohort of the dataset. Of the 125 claims within the dataset, 106 had age attributes associated with the record. The distribution of claims by user age and gender is shown in [Fig. 3](#). Note that the total sample size is 104, as two of the observations with age information did not have a gender attribute.

As noted above and in previous work, adjustments to the claims significantly reduce the representation of the younger cohort in claim activity. When claims are adjusted by certain denominators that control for the level of use, the representation of the younger user cohort significantly diminishes. This is shown in [Fig. 4](#), where the claims per 1000 trips are far more level across the different user age groups.

[Fig. 4](#) shows that when the age of the user by the claim is controlled for by the number of trips taken by the age cohort, the contribution of younger users is reduced on a relative basis. This supports the concept that the higher claims per 100 insured vehicle years found within carsharing overall is more a function of the mass of younger users rather than exceptionally risky behavior of this cohort relative to the general population of the same age.

Other data can yield insights on the patterns of carsharing use across key age cohorts, which show some limited variation. The value of this assessment is that it shows that the difference in age-related patterns is generally not a function of use. All carsharing

Figure 4 Age of user by number of carsharing claims per 1000 trips.

Figure 5 Carsharing trip distance by age, distance, day of the week, and month.

users appear to exhibit the same trends in the trip distance over the course of the year, where the distance of trips slightly increases during the summer and increases on weekends. The absence of key distinctions is shown in [Fig. 5](#).

Finally, usage patterns in terms of carsharing trips over the year also show limited distinctions by age cohort. For example, as shown in [Fig. 6](#), when evaluating carsharing trips by month, day of the week, and within the same age cohorts presented in [Fig. 5](#), the key distinction is a notable drop in trip activity among the younger age group of 18-25-year olds.

Here, the impact of summer vacation is clearly evident, where a drop in trip count may contribute to a drop in claims given the contribution younger members made to claim activity within the carsharing dataset.

The data presented show that the measurement of carsharing risk depends on the unit of measurement. This may be intuitive, but it is worth emphasizing when evaluating risks within the domain of shared mobility use. Under traditional industry approaches to risk measurement, namely the use of claims per 100 insured vehicle years, carsharing performs worse than the general population insuring their personal vehicles. However, this is due to the nature of the user and the system's relationship to the vehicle. Carsharing vehicles are used more intensely than personal vehicles, and a large share of vehicle users are within an age category that exhibits higher overall industry risk. When several use factors control for the amount for use, the results show that the risk of carsharing users is relatively equal on a per-trip basis across the younger age cohort.

Figure 6 Trips by month, day of the week, and age by month.

Conclusion and Discussion

The study findings, which are also evaluated in the related study (Shaheen et al., 2016), suggest that metrics applied in the traditional insurance industry are not necessarily the best metrics to be applied to the carsharing industry. Carsharing safety, when controlled for by the level of use and measured by claims, did not vary across age cohorts as measured in the traditional auto insurance industry. Inevitably, the user profile of any system must be considered, and if the user profile is balanced toward riskier cohorts, then appropriate adjustments of assessment must be considered. But notably, this is a function of the cohort itself, rather than the services delivered, which otherwise aid the welfare of the cohort it is serving. Carsharing's insurance experience has been inevitably challenging, but its role in pioneering the relationship between shared mobility and the insurance industry is indisputable. Nevertheless, the evolution of the larger shared mobility ecosystem requires different metrics for each modality employed by a broader population, reflecting modal differences and unique user populations. These considerations may be relevant through the assessment of other sectors of the shared mobility industry. Such a cross-industry understanding is important. Failures to appropriately manage risk and relationships with the insurance industry can shut down an organization or significantly raise costs in industry. A better understanding of insurance pricing in carsharing and the larger shared mobility ecosystem can lead to better risk management within the industry, which will deliver greater service and cost stability to shared mobility users.

Acknowledgments

This article was based on a study conducted by [Shaheen et al. \(2016\)](#) that was originally funded by Assurant. Co-author Diwen Shen conducted data cleaning and analysis in support of the discussion and analysis within this article. Arupa Adikary also contributed background research in support of this article. Six carsharing operators provided the data necessary to conduct this research. The discussion, findings, and conclusions are the responsibility of the authors of this article.

Introduction

Carjacking is a type of motor vehicle theft. However, its specific definitional elements exhibit major cross-national differences. National differences are found in (1) the type of motorized vehicle included (e.g., cars/trucks, watercraft, scooters, and/or rail transport), (2) individuals involved (e.g., strangers, non-authorized persons, or no restrictions on offender-victim relationship), (3) occupancy level (e.g., occupied vehicles, unoccupied vehicles, or both), (4) offense outcome (e.g., attempted or completed thefts), and (5) offender motivation (e.g., "joyriding," sale/trafficking of vehicles, or vehicle parts). The level of physical threat utilized and injury to the victim are other factors that influence the more general classification of carjacking as a property crime (e.g., theft without injury or threat) or violent crime (e.g., robbery, assault/battery and/or murder) across nations.

This essay examines these definitional issues around carjacking, motivations and methods of acquisition, its estimated national prevalence, and socioecological factors associated with these crimes. Situational crime prevention practices are also discussed for reducing the prevalence of carjacking and other transportation-related crimes.

Definitional Issues

Most countries do not have separate criminal statutes for carjacking and there is no uniform definition of these offenses across nations. Instead, estimates of the nature and prevalence of carjacking are often derived from statistics on other crime categories (e.g., auto theft, robberies) or through analyses of offense-related elements identified in surveys of crime victims. The United States National Crime Victimization Survey (NCVS) illustrates the use of offense-related elements by defining carjacking as "a completed or attempted robbery in which a car or other motor vehicle was taken or an attempt was made to take it and the offender was a stranger to the victim" (Klaus, 2004).

Compared to other crimes, carjacking is essentially a motor vehicle theft that involves an occupied vehicle and the threat or use of violence against the driver (Cesar and Decker, 2017). Similar to traditional robbery, carjacking is a transactional crime. Carjackers must confront victims and demand compliance through force or the threat of force. They also take advantage of an immediate opportunity and rely on speed and stealth to approach their victims. However, carjacking differs from other robbery situations because the targeted vehicle is mobile, the victim is removed from the vehicle, and there is a greater risk of physical injury and victim resistance when the vehicle is used as both a shield and a weapon against the offender (Copes et al., 2011; Jacobs, 2012). Unlike in

thefts of unoccupied vehicles, the carjacker must confront the vehicle's driver, gain compliance, and contend with a shorter window of opportunity to commit the offense.

Typologies of Carjacking

Several typologies or classification system have been used in past research to identify different types of carjacking. These include the classification of carjacking by (1) level of planning and motive and (2) method of acquisition.

Level of Planning and Motive

Young and Borzycki (2008) suggest that carjacking can be differentiated along two continuums: level of planning (i.e., organized vs. opportunistic) and motive (i.e., instrumental vs. acquisitive). The primary characteristics of these four types of carjacking based on their different levels of planning and motive are shown in **Table 1** and summarized as follows.

"Organized and instrumental carjacking" involves some planning before the offense. The vehicle is taken in order to facilitate another criminal offense. For example, the vehicle may be taken to fulfill a "smash and grab" heist (e.g., running cars into ATM machines or the front windows of convenience stores and other commercial businesses) or as temporary transportation to conduct a drive-by shooting. The vehicle itself is of no direct financial value to the offender and will likely be abandoned after serving its intended purpose.

"Organized and acquisitive carjackings" are also characterized by prior planning, whether in the type of vehicle targeted or in the method of acquisition. The goal is to obtain a vehicle for its direct financial value and sell it as soon as possible to a willing buyer or to a chop shop (who will strip the vehicle to sell its parts). For example, carjackers may target vehicles of specific makes and models because there is a market demand for such vehicles (Young and Borzycki, 2008). The market value of the particular type of vehicle selected for "jacking" could be based on the popularity of the vehicle or the usefulness of its parts.

"Opportunistic and instrumental carjackings" involve no real prior planning. As the name suggests, these incidents are entirely motivated by a potential offender recognizing a window of opportunity and acting upon it. The carjacker in this scenario is very likely unarmed and acting alone. The vehicle is taken because it caught the offender's attention, whether for its value or for the perceived opportunity to act. The stolen vehicle will be sold later or stripped for parts, but there was no specific market in mind when the vehicle was taken (Young and Borzycki, 2008).

"Opportunistic and acquisitive carjackings" are distinct because they do not involve any real planning or any financial motivation. Such events are typically precipitated by an offender or group of offenders seeing an opportunity and taking the vehicle. The vehicle may be taken for a joyride. It may be taken to boost one's social status or to punish another for flaunting his or her material wealth. However, the vehicle itself is not taken for any future purpose and is likely abandoned shortly after.

Method of Acquisition

When classifying carjackings by their method of acquisition, prior research has identified five distinct categories. Each has particular features that identify their unique signatures.

The "bump-and-rob" carjacking involves multiple offenders who initiate the criminal incident by ramming the target vehicle with another vehicle. This is usually done from behind and at a low speed. When the driver exits the target vehicle to check for

Table 1 Planning and motivation classification for carjacking

<i>Level of planning/Motivation</i>	<i>Attributes</i>
Organized/Instrumental 	Vehicle taken to facilitate other crime Vehicle has no direct financial value Vehicle abandoned after purpose is served
Organized/Acquisitive 	Vehicle targeted for direct financial benefit Vehicle sold as soon as possible Targeting centers on market demand
Opportunistic/Instrumental 	No prior planning Vehicle simply caught offender's attention Vehicle will be sold later but vehicle's market did not prompt the carjacking Likely a single, unarmed offender
Opportunistic/Acquisitive 	No future purpose intended for vehicle Vehicle is abandoned shortly after Often motivated by respect or social status

Source: Adapted from Young and Borzycki (2008)

damage or to request the at-fault driver's insurance information, one of the other offenders jumps into the target vehicle and both vehicles quickly drive away.

The "trust violation" occurs when the carjacker has been granted possession of the vehicle or allowed access to the driver seat but is expected to return the vehicle. One example of these incidents is when a carjacker test drives a vehicle for sale and forces the owner or sales agent to exit the vehicle after leaving the lot. A valet parking agent (or person pretending to be one) who takes a customer's car and does not return it is another example of these trust violations.

The "normalcy illusion" method involves a carjacker approaching the target in a manner that initially seems harmless (Jacobs, 2012). The goal is to lull the target into a false sense of security by pretending to engage in a nonthreatening task, such as asking for help, cigarettes, directions, or the time. The key is that normal people would not feel threatened by such seemingly innocuous encounters. In addition, the normalcy illusion reduces the amount of attention from witnesses who may interfere or contact law enforcement. The carjacker gets close to the driver and either draws a weapon or simply pulls the distracted driver from the vehicle.

The "blitz attack" is another method of acquisition in carjacking scenarios. In contrast to the stealth underlying the normalcy illusion method, the blitz attack utilizes speed, shock, and force (Jacobs, 2012). Blitz attacks are risky, and timing is critical to success. The goal is to catch the driver off-guard and leave him or her with no choice but to comply. Examples of blitz attacks include running up to the vehicle at a red light and brandishing a weapon. Another example is following a target until the vehicle is parked, blocking the vehicle's escape with another vehicle, and then running up to one of the windows.

"Other" methods of acquisition in carjacking situations involve an assortment of approaches to immobilize the motorist through physical or verbal means. These include such activities as running motorists off the road, pretending to be a police officer, pretending to be a hitchhiker, blocking roads with various objects (e.g., bricks, stones, oil drums, or traffic cones) and faking a car accident or flat tire in order to prey upon those who stop to help.

Police reports and interviews with actual carjackers provide qualitative data to illustrate these different methods of acquisition in carjacking situations. The following descriptive accounts of carjacking methods have been constructed and rewritten from short, abbreviated summaries of cases within these data sources:

Bump-and-Rob

- Two male suspects followed a male victim down a side-street before ramming the victim's vehicle with their own. The victim pulled over and exited his vehicle to confront the suspects. After a brief confrontation, one suspect drew a gun and fired several shots. After the victim went to the ground, the other suspect entered the victim's truck and sped off.
- A female victim traveled on an interstate highway when the suspect's vehicle flashed its headlights at her, signaling her to pull over. The suspect followed the victim off the highway and then rear-ended her vehicle. When the victim exited her vehicle, the suspect pointed a gun at the victim's head, took her keys, and drove away in her vehicle. The suspect's partner drove the ramming vehicle away.

Trust Violations

- A salesman at a car dealership presented a vehicle to the male suspect and female suspect. Both suspects sat in the vehicle before pushing the salesman away. The suspects then sped off the lot, nearly striking a person as they fled.
- A male victim drove to the entrance of an upscale restaurant. The male suspect approached and asked if the victim wanted to have the valet (i.e., parking attendant) park his vehicle. The victim handed his keys to the suspect. Later, the victim went to retrieve his vehicle and learned both that the staff had no record of his vehicle and that no one matching the suspect's description worked there.

Blitz Attack

- A male victim slowed his vehicle for a red light when the suspects' vehicle pulled in front of him. One suspect exited the vehicle while holding a gun and told the victim to "get the f*ck out of the car." The suspect then entered the victim's vehicle and fled while the second suspect drove their vehicle.
- A teenage driver waited at a traffic signal after borrowing his friend's truck. A male suspect entered the truck and began striking the teenager with his fists in order to force him to exit from the vehicle. After the driver exited the vehicle, the suspect moved into the driver's seat and drove away.

Normalcy Illusion

- An elderly victim waited in his car while his wife shopped inside a store. The male suspect approached the victim's car and asked for the time. The suspect returned shortly after to ask for spare change. The suspect then returned a third time, this time with a gun, and threatened to shoot the victim, if he did not exit the vehicle. The victim stalled but eventually complied. The suspect then drove away.
- Two male suspects approached a couple in a parking lot. One suspect asked the couple for cigarettes. One victim gave the suspect a cigarette, but the suspect then drew a gun and pointed it at the male victim. The other suspect demanded the car keys and the female victim's purse. The suspects then drove away in the vehicle.

Other Methods (Police Impersonator)

- Four victims parked outside a liquor store. The driver went inside. A male suspect approached the other three victims and claimed he was a police officer who urgently needed to respond to a bank robbery. The victims exited the car and allowed the suspect to drive away. The victims then flagged down a police officer and learned that no such bank robbery had occurred.

Prevalence and Characteristics of Carjacking

Definitional and methodological differences limit cross-national estimates of the prevalence and nature of carjacking. The problems are compounded by the general lack of national police data on carjacking and the need to extrapolate patterns from other crime categories (e.g., vehicle thefts, robberies) and incident attributes in victimization surveys. What we know about the prevalence of carjacking and the socioecological factors associated with it are summarized as follows.

Prevalence

Compared to the prevalence of motor vehicle thefts and armed robberies, available data from several nations and major cities indicate that carjackings are relatively rare. In the most comprehensive study of carjacking using the United States national victimization data, [Klaus \(2004\)](#) estimated that an average of 34,000 carjackings occurred in the United States annually from 1993–2003. The victimization rate for carjacking was 17 per 100,000 population. In contrast, rates of auto theft victimization (910 per 100,000) and personal robbery (250 per 100,000) were substantially higher during this time period ([Rennison and Rand, 2003](#)). Among US cities, the Chicago police department reported over 1000 carjacking incidents in 2017. In St. Louis in 2017, more than 250 carjacking incidents were reported to the police. News accounts estimate that Detroit had over 700 carjackings in 2014.

Estimates of the prevalence of carjacking vary widely across other nations. For example, South Africa has reportedly one of the highest rates of car “hijacking” in the world, with an estimated 11,000 of these incidents in 2014. The rate of these incidents in 2000 was 34 per 100,000 residents ([Davis, 2003](#)). Within the United Kingdom and Australia, carjacking is rare, representing less than 1% of vehicle thefts. In contrast, the majority of thefts of insured motor vehicles in Mexico are taken “with violence” ([Espinoza, 2019](#)) and the carjacking of tourists also appears to be a major concern in other nations (e.g., Brazil, Costa Rica, France, India, Spain). Across all world regions, there is a general belief that carjacking has increased over the last two decades in large part because technology is making it more difficult to enter, “hot wire,” and steal unoccupied vehicles.

Socioecological Characteristics

Similar to other crimes, carjacking is not randomly distributed over persons, places, and situations. Instead, particular types of people, places, and situational contexts are associated with higher risks of carjacking than others.

Based on previous studies, carjackers are typically young males. Black and Hispanic persons are over-represented among victims of these crimes within the United States ([Klaus, 2004](#)). Most carjacking incidents involve multiple offenders, the use of weapons to gain victim compliance, and some physical injury to the victim.

In terms of its social ecology, carjacking is spatially concentrated within densely populated urban areas. They occur disproportionately at night in open areas (e.g., on the street or near public transportation) and near commercial places (e.g., stores, gas stations). Within economically disadvantaged areas in large cities, carjacking may be especially common for fulfilling multiple extrinsic and intrinsic rewards, including economic opportunities, thrill-seeking, and status-enhancement of one’s street reputation ([Cesar and Decker, 2017](#); [Jacobs et al., 2003](#)).

Street Culture and Carjacking

Street culture plays a large role in carjacking in large urban areas within American society. The street culture emphasizes a pleasure-driven lifestyle, respect, and going with the flow ([Jacobs et al., 2003](#)). Participants must subsidize this hedonistic lifestyle, but they often have limited access to legitimate means of acquiring resources. This lifestyle centers on drug and alcohol consumption, material pursuit, reckless spending, and sexual conquests. The cash-intensive nature of these activities creates a perpetual need for money. Carjacking can help support this lifestyle by providing a means of obtaining money without having to rely on an ordinary job, but the increased resources acquired through successful carjacking may finance more intensive partying, again fueling the need for more money ([Jacobs et al., 2003](#)). Street culture encourages living in the moment. Criminal offenses might arise from circumstances beyond individuals’ immediate control and force them to participate (e.g., participating in a carjacking begun by an associate). Street culture encourages thrill-seeking, which might be accomplished through the adrenaline rush of overcoming danger or using force to get one’s way. Carjacking provides both.

Another important aspect of American street culture involves a moralism centered primarily on respect. In the streets, affronts must be met with punishment, and no affront is too trivial ([Jacobs et al., 2003](#)). Those who flaunt their material possessions run the risk of offending those who have less. Carjacking facilitates the purpose of retaliation by allowing offenders to put social violators

“back in their place” by breaking the violators’ feelings of invincibility (Jacobs et al., 2003). At the same time, flaunting material wealth is about one-upmanship. Joyriding in a jacked vehicle allows the offenders to become flaunters themselves and to reassert their dominance by flaunting their conquest to friends and neighbors alike.

Prevention Activities

Previous studies have identified several types of prevention activities to reduce individual’s personal risks of being carjacked and the offender’s motivation for committing these crimes. Examples of these control strategies include those that focus on the general methods of situational crime prevention (SCP).

Situational Crime Prevention

Situational crime prevention is a criminological perspective rooted in criminal opportunity theories. The general idea is to alter criminal opportunity in order to deter rational offenders. Carjackers are opportunistic offenders. Under SCP, these are the kind of offenders who can be deterred.

As shown in Fig. 1, SCP has five main approaches to reducing criminal opportunity (Brown, 2015; Clarke, 1995, 2010). First, increase the effort required to carry out a crime. Second, increase the risks involved in completing a crime. Third, reduce the expected rewards associated with the crime. Fourth, remove excuses that an offender would use to justify his or her actions. Finally, reduce the provocations that would tempt a person to transition from a potential offender to an actual offender. Specific SCP strategies aimed at reducing carjacking are summarized as follows.

Increased Effort for Carjacking

Increasing the effort for carrying out carjacking is one of the first steps in prevention. “Target hardening” strategies, those that make it more difficult for suspects to gaining access to vehicles and remove them without the owner’s permission, should be a priority. Establishing greater control over access points to facilities and screening entrants to various locations (e.g., parking garages, commercial business lots, gated communities) are some general ways of increasing the effort for carjackers. Particular examples of these strategies for target hardening include the following:

- Enhance the public’s knowledge of the common methods used by carjackers (e.g., bump-and-rob’s, trust violations, blitz attacks). An aware public can decrease the physical opportunity for these offenses.
- Increase the installation of remote “kill switches” (e.g., engine/ignition immobilizers) and GPS tracking devices to limit the opportunity for unauthorized use of motor vehicles.
- Improve and apply other monitoring sensors and facial/fingerprint recognition technology to restrict the pool of eligible drivers of each motorized vehicle.

Figure 1 Situational crime prevention strategies. Source: Adapted from Clarke (1995)

- Place barriers and gates in all major parking structures to reduce the unabated pathways for exiting from these structures.
- Hire security in public places (especially at night) to escort customers to their vehicles. Once you reach your vehicle, enter quickly, lock your doors, and drive away immediately.

Increase Risks for Carjacking

In addition to injury and death from the incident itself, the primary risks for carjackers are the threat of criminal punishment. From a crime deterrence perspective, the threat of punishment deters crime when it is perceived as swift, certain, and severe. Swift punishment for carjackers may derive from acts of self-protection by victims and their “strategic resistance” (Miethe and Sousa, 2009). Within many US cities, the mere threat of an armed confrontation with the vehicle’s driver may sufficiently deter these crimes. Several particular ways to increase the offender’s risks for carjacking through the swift, certain, and severe threat of criminal sanctions include the following:

- Increase the use of visual surveillance technology in public spaces (e.g., parking lots, streets/highways) to improve the speed and likelihood of carjacker’s identification and arrest.
- Increase the natural surveillance in public spaces (especially in more isolated areas at night) through enhanced lighting and environmental redesign (e.g., remove excessive foliage that decreases the visibility of these places).
- Increase the severity of criminal punishment for carjacking by prosecuting carjackers in federal court, where both the certainty of conviction and severity of punishment are higher than in most state courts. Arrest and prosecute carjackers for multiple offenses, including vehicle theft, personal robbery, and assault.

Reducing Rewards for Carjacking

Carjackers are motivated by various anticipated rewards that derive from their actions. The financial motivations associated with carjacking may be reduced through the following practices:

- Remove expensive and portable items (e.g., cell phones, briefcases, and luggage) from unoccupied vehicles that may attract economically motivated and opportunistic carjackers.
- Tighten local, state, and national controls over vehicle licensing/registration and the marketing of vehicle parts. If carjackers are less able to sell their stolen vehicles or parts from them because of these controls, the financial motivations and anticipated economic rewards may be diminished.

Reducing Provocations

Carjacking is committed by people who either lack the economic resources to purchase a motor vehicle or who seek alternative ways of getting them for material (i.e., economic) and nonmaterial motives (e.g., thrill, peer pressure, feelings of empowerment). Based on the diverse motivations, another set of strategies to reduce carjacking involves decreasing the different provocations that often underlie these crimes. Particular ways to decrease these provocations for carjacking include the following:

- Increase meaningful economic opportunities for the disadvantaged to reduce the profit-motivation for carjacking.
- Increase public service campaigns for juveniles and young adults that promote personal responsibility, decrease susceptibility to peer pressure, and encourage self-control when exposed to immediate situational opportunities for joyriding and carjacking.

Removing Excuses

Many offenders, including carjackers, are able to commit criminal acts because they can rationalize and excuse their actions. The following excuses that carjackers often use to justify their conduct may be nullified by the following actions and counter evidence:

- Reduce drugs and alcohol abuse to decrease impaired judgment caused by substance abuse and the denial of responsibility for one’s actions because of this impairment.
- Negate the excuse of “denial of injury” through educational campaigns that demonstrate the adverse economic, physical, and psychological consequences of carjacking on its victims.
- Counter the offender’s excuse of “blaming the victim” (e.g., belief that the victim was somehow responsible by being careless or provoking the incident) by increasing public knowledge that victim carelessness is not a legal excuse for criminal liability in carjacking incidents.

Summary and Conclusions

Carjacking is a type of motor vehicle theft that often has financial, physical, and psychological consequences for its victims. It is motivated by opportunity, financial gain, and nonmaterial factors such as thrill, peer pressure, and feelings of empowerment. With increase in technology that both enhance and inhibit criminal opportunities, efforts to control carjacking through prevention strategies will have to evolve over time. However, situational crime prevention approaches offer an important perspective for

reducing carjacking and other transportation-related crimes because they focus on doing something about both limiting criminal opportunities in everyday life and decreasing offender's motivations for committing these offenses.

Introduction

An airplane operation in space is always performed under the risk of collision. An airplane is a dynamic object that usually moves and maneuvers with high speed. Equipment failures or airplane deviation from preplanned trajectory can lead to a collision with an object or other airspace users (Ostroumov and Kuzmenko, 2018). Initially, airplane flights are planned with collision-free trajectories within the network of flight routes. Air traffic management is performed under Air Traffic Controller (ATC) operation and usage of specific flight leveling. Flight levels, measured from mean sea level (MSL), guarantee safe separation between airplanes within one flight route. ATC clears specific flight level for each airspace user and is responsible for nonconflict planning of air traffic within predefined airspace volume. Pilots need to follow all ATC instructions; therefore, a mid-air collision may be the result of a human factor of an ATC or a pilot.

Ground and artificial constructions are other important threats to airplane operations. During take-off or landing phases, an airplane is located at low altitude. Thus, buildings, high-altitude artificial constructions, electrical wires, or trees may be a danger for operation in case of poor visibility. An airplane is equipped with a terrain awareness system in order to increase situational awareness of a pilot about dangerous obstacles. Nowadays, terrain awareness may be supported by the ground proximity warning system (GPWS), enhanced ground proximity warning system (EGPWS), or terrain awareness and warning system (TAWS).

Mid-Air Collision Avoidance

The constant growth of a number of airplanes in use increases the airspace demand and increases the mid-air collision risk. Traffic alert and collision avoidance systems (TCASs) are used onboard an airplane to detect and avoid near mid-air collisions between airplanes. TCAS is based on secondary surveillance radar (SSR) principle and is fully independent of any ground equipment (Livadas et al., 2000).

International regulations provide three available TCAS types, namely, TCAS I, TCAS II, and TCAS III.

TCAS I detects airspace users equipped with air traffic control radar beacon system (ATCRBS) transponders and indicates their locations to pilot in order to improve situation awareness. Basically, TCAS I provides only traffic advisory (TA) for nearby airspace users. TCAS I is widely used in general aviation and is mandated for usage onboard all aircraft with more than 10 and less than 31 passenger seats.

TCAS II provides TA and supports near mid-air collision detection and avoidance by coordinated maneuver in a vertical plane guided by resolution advisory (RA). TCAS II is mandated in European airspace for a commercial airplane with more than 19 passengers (or 30 passengers in the airspace of the United States) or a maximum take-off weight exceeding 5700 kg (or 15,000 kg in the United States).

TCAS III should support TA and RA in both vertical and horizontal planes. However, due to technical limitation of equipment, mostly in pure accuracy of bearing measurement, TCAS III is still under the development stage.

The TCAS family is based on independent surveillance function (Fig. 1). TCAS surveillance equipment generates an interrogation signal at 1030 MHz similar to secondary surveillance radar interrogation and emits them via two antennas placed on the top and bottom parts of an airplane. Both antennas support surveillance in different volumes: above and below an airplane to cover the whole airspace around them. Interrogation signals will be received by an ATCRBS antenna after a time of radio waves propagation in space. ATCRBS transponder automatically generates and transmits a reply signal at 1090 MHz after fixed 3.0 μ s delay. Reply signal in mode "S" of ATCRBS contains a digital message that includes a unique airplane code (24 bits of data), a barometrical altitude of an airplane (MSL) and some other technical data. A reply will be received by a

Figure 1 Surveillance function of TCAS.

Figure 2 TCAS polar coordinate system.

directional antenna of TCAS. The time of the radio signal propagation makes it possible to calculate an exact distance to another airspace user:

$$D = 0.5c(t - t_{\text{ATCRBS}})$$

where $t_{\text{ATCRBS}} = 3.0 \mu\text{s}$ is a delay in ATCRBS transponder; t is a time between transmission interrogation signal and receiving a reply; $c = 3 \times 10^8 \text{ m/s}$ is a speed of electromagnetic wave propagation.

The directional antenna of TCAS measures the bearing of a reply signal. The bearing is the angle between an airplane longitudinal axis and direction to the ATCRBS transponder in the horizontal plane measured clockwise. Distance and bearing localize ATCRBS transponder in a polar coordinate system with a reference point at TCAS antenna locations (Fig. 2). The relative altitude is calculated as the difference between barometrical altitude from Air Data System and data of barometrical altitude from the digital message of the ATCRBS transponder. Also, surveillance equipment supports observation one time per second.

Unfortunately, the bearing measurement is not sufficiently accurate for horizontal collision avoidance. A common error of bearing measurement in TCAS does not exceed ± 5 degree, but in some cases, the configuration may exceed ± 30 degree. Low accuracy of bearing measurement makes realization of collision avoidance in a horizontal plane impossible and holds TCAS III equipment under the research stage.

TCAS II uses air traffic data for collision detection and avoidance. TCAS II algorithm tracks each airspace user-collecting airplane coordinates with the same identification code and extrapolates their trajectories (Fig. 3). TCAS II estimates closest points of approach (CPA) for both predicted trajectories and detects horizontal and vertical distances between CPA A and B. Obtained

Figure 3 Conflict detection in TCAS II.

Figure 4 Structure of TCAS II.

distances are compared with the required separation minimums between airplanes. In the case of separation being reduced toward or below the required minimum, TCAS logic detects risk of mid-air collision and estimates time of flight to CPA (τ) (Rand and Eby, 2004; Munoz et al., 2013). Due to the difference in airspace structure and separation minimums, basically, there are two commercially available versions of TCAS II: version 6.04 (developed for US implementation) and version 7.1 (for European airspace). TCAS II generates two safety areas according to τ scale: Caution area within 20–48 s and Warning area 15–35 s (exact time depends on the sensitive level or airplane altitude). Location of CPA in caution area generates TA and location in warning area generates RA.

Basically, TCAS II includes a processor unit that is connected to two directional antennas (bottom antenna may be replaced with omnidirectional antenna) (Fig. 4). In common case, TCAS is connected to ATCRBS transponder of mode S and has a control panel in the cockpit. An ATCRBS transponder has two omnidirectional antennas. As input data, TCAS II uses barometric altitude and airspeed from an air data system, absolute altitude from low range radio altimeter (LRRA), heading from attitude and heading reference system, and some data from TAWS that blocks TCAS logic in case of conflict with a ground surface. Data from TCAS will be indicated on an electronic flight instrument system (EFIS) and is used in a flight management system (FMS). Aural annunciations can be shared with the audio system of the airplane via the audio control panel. Also, some TCAS data is stored in the flight data recorder.

TCAS data can be indicated by EFIS on a modern airplane cockpit design or via modified vertical speed indicator and traffic display (VSI/TDI), or radar display in an old-fashioned cockpit design. Mostly, all modern large airplanes are equipped with EFIS that includes primary flight (PFD), navigation (ND), and system displays (SD) (Fig. 5). Traffic data is indicated on ND. RA is

Figure 5 TCAS II indication. (A) Vertical speed indicator and traffic display (VSI/TDI). (B) Electronic Flight Instrument System.

indicated on the scale of vertical speed indicator on PFD. Air traffic is depicted on PFD using four types of symbols depending on threat value as follows:

- An unfilled diamond indicates not dangerous traffic. Predicted trajectories of these airplanes are not crossing, or crossing, but horizontal and vertical separation minimums at CPAs are more than enough for safe clearance, or airplanes are at the long distance.
- A filled diamond depicts nonconflict or proximate traffic that is located close to an airplane (within a cylinder with radius 6 NM and height ± 1200 ft. from current airplane altitude).
- A filled yellow circle shows intruder airplane. Predicted trajectories of airplanes are crossing and horizontal and vertical separations between CPAs are less than required for current airspace structure, but time of flight to CPA is within a caution area.
- A filled red square depicts intruder that caused RA and time of flight to CPA is within the warning area.

Each air traffic symbol is accompanied with relative altitude number between an airplane and airspace user in hundreds of feet above (+) or below (–) an airplane. Down or up arrow indicates a vertical speed trend for climbing or descending airplanes with the speed more than 500 ft./min.

If airspace user is detected as an intruder and time of flight to CPA is within caution area, an airplane will be depicted as a yellow circle with simultaneous aural advisory generation for pilots “Traffic, traffic”. This advisory means that we have reduced separation minimum in CPA with the depicted airplane, time of flight to CPA is less than 20–48 s and in 10–13 s RA will be generated. At this scenario, pilots need to be prepared for a possible RA and can try to make visual contact with the intruder. However, no maneuvers shall be done.

In case the CPA is located within the warning area, TCAS II will initiate a conflict avoidance algorithm that choose collision avoidance maneuver and estimates minimum required vertical speed. After approving of collision avoidance maneuver by TCAS of intruder airplane, pilots of both conflict airplanes will receive coordinated RA. RA is indicated in the form of red and green areas on the scale of vertical speed indicator. The red area indicates prohibited and green—desired vertical speed. Simultaneously with RA, the intruder is depicted as a red square symbol. Aural warnings are connected with a particular vertical speed required in RA (Table 1).

In the most cases “Climb, climb” or “Descend, descend” are initial aural alerts in TCAS II that require a pilot to initiate climbing or descending with a vertical speed not less than 1500 ft. (450 m)/min. Collision avoidance algorithm in TCAS II uses a

Table 1 Aural alerts in RA of TCAS II version 7.1

Upward sense		Downward sense	
Required vertical speed (ft./min)	Aural warning	Required vertical speed (ft./min)	Aural warning
1500	Climb, climb	–1500	Descend, descend
1500	Climb, crossing climb; Climb, crossing climb	–1500	Descend, crossing descend; Descend, crossing descend
2500	Increase climb, increase climb	–2500	Increase descent, increase descent
1500	Climb, climb NOW; Climb, climb NOW	–1500	Descend, descend NOW; Descend, descend NOW
0	Level off, level off	0	Level off, level off
No change	Monitor vertical speed	No change	Monitor vertical speed
From 1500 to 4400	Maintain vertical speed, maintain	From –1500 to –4400	Maintain vertical speed, maintain
From 1500 to 4400	Maintain vertical speed, crossing maintain	From –1500 to –4400	Maintain vertical speed, crossing maintain

cylindrical model of an airplane with a CPA in the center. In case of crossing cylindrical models in CPA, TCAS puts the word “crossing” in aural alert to indicate a threat of possible mid-air collision. If the speed of 1500 ft./min is insufficient for safe clearance in CPA, TCAS II generates RA for speed increasing up to 2500 ft. (760 m)/min, which is accompanied with aural alerts “Increase climb, increase climb” or “Increase descent, increase descent”. During conflict avoidance, TCAS may change the direction of maneuver that will be indicated in issued aural warning “Climb, climb NOW; Climb, climb NOW” or “Descend, descend NOW; Descend, descend NOW” with a minimum required vertical speed of 1500 ft./min. Warning “Level off, level off” is issued when safety separation in CPA is reached and the airplane has to stop changing vertical speed and has to start a horizontal flight. Warning “Monitor vertical speed” does not require changing vertical speed, but a pilot needs to look into vertical speed indicator and to locate some prohibited range on the scale. Alert “Maintain vertical speed, maintain” usually is connected with a wide range of possible values for vertical speed from 1500 ft. (450 m) up to 4400 ft. (1340 m)/min. Bigger values inform about closeness of location to CPA and dangerous conflict states. After successful conflict resolution, TCAS generates aural alert “Clear of conflict” and the pilot can return to the previous cleared flight level.

According to regulative documents, pilots have to respond to initial RA within 5 s and for subsequent RA within 2.5 s. After the first RA generation, pilots need to report to the ATC about TCAS II operation. The airplane will be out of ATC control within the time of RA up to aural alert “Clear of conflict.” A maneuver contrary to the RA is strongly prohibited.

At low absolute altitude, some RAs are inhibited in order to avoid airplane conflict with a ground surface:

- Alert “Increase descend” is inhibited below 1550 ft. (470 m).
- Alert “Descend, descend” is inhibited below 1100 ft. (335 m).
- All RA aural alerts are inhibited below 1000 ft. (305 m).
- All TCAS II aural alerts are inhibited below 500 ft. (150m).

Nowadays, TCAS II is mandatory onboard equipment that plays the role of “last” safety insurance system in case of a mid-air collision. Numerous disadvantages of current TCAS stimulate the development of TCAS technology. The collision detection algorithm in TCAS is grounded only on predicted trajectories and a set of geometrical tests that generate numerous false alarms in case of maneuvering airplanes. Poor accuracy of surveillance data and a relative indication of air traffic can lead to misunderstanding of conflict geometry by pilots.

Support of RA onboard some airplanes has been integrated into the autopilot system. For example, Airbus autopilot/flight director supports the airplane to automatically follow the RA issued by TCAS II. Also, an airplane may be equipped with TCAS alert prevention algorithms that have been introduced by Airbus in order to reduce the amount of false RAs.

The concept of new ACAS X is currently under the development stage by an international team of researches (Jeannin et al., 2015). Future system will use Automatic Dependent Surveillance-Broadcast data to increase surveillance performance and decrease the workload of onboard ATCRBS transponders (Kastelein and de Haag, 2014). Collision detection and avoidance will be grounded on statistical algorithms that will decrease the number of false alarms and will be safer in mid-air collision avoidance (Gardner et al., 2016; von Essen and Giannakopoulou, 2016). Also, ACAS X will be compatible with the free routes concept and will support integrated remotely piloted aircraft systems in controlled airspace.

Terrain Collision Awareness

Airplane flight at low altitude is always connected with a threat of collision with terrain. Modern airplanes are equipped with some kind of TAWS in order to reduce the risk of collision with terrain. TAWS improves situational awareness of pilots providing an aural and visual representation of potential dangerous relief and danger descend scenes of the airplane (Mozdzanowska et al., 2008).

Historically, the terrain collision awareness function has been implemented in a ground proximity warning system (GPWS). GPWS was mandated by the Federal aviation administration (FAA) since 1974 for all airplanes flying in the US airspace. GPWS uses data from various sensors onboard an airplane to detect dangerous descent of the airplane. Typical GPWS uses altitude above ground level (AGL) measured by low range radio altimeter (LRR), barometric altitude and descent rate from an air data system to detect near-accident conditions. Accident detection algorithm in GPWS compares current values of sensor measurements with allowed boundary levels. Commonly, GPWS compares two parameters simultaneously. Thus, the near-accident state is defined as a closed region (Fig. 7). Deviation of measured values to dangerous area initiates visual and aural warning to pilot about danger state of flight. Pilots should take action to move some parameters out of warning area in order to avoid collision with a ground. Also, GPWS uses landing gear status and flaps location to detect the phase of airplane flight and to reduce false alarms in case of landing. In addition, GPWS uses data from the instrument landing system (ILS) to detect significant deviation from glideslope during airplane landing. GPWS helps to decrease the number of incidents in case of controlled flight into terrain. However, GPWS has a serious limitation, because LRR cannot detect terrain or obstacles ahead of the airplane. GPWS warning is grounded on current AGL only. The solution to this problem has been found in 1990 using digital computing equipment onboard of the airplane.

Enhanced ground proximity warning system (EGPWS) includes all GPWS functionalities together with forward-looking terrain avoidance (FLTA) function (Theunissen et al., 2005; Zhang et al., 2013). Nowadays, EGPWS can be used as a synonym of TAWS. The internal memory of TAWS includes worldwide terrain, obstacles, and airport digital databases. TAWS uses airplane location from global navigation satellite system (GNSS) (or attitude and heading reference system, in case of GNSS lock) together with altitude and ground speed data to predict airplane movement (look ahead) and compares airplane flight path with available relief model and

Figure 6 Topographic and relative altitudes modes of terrain indication in ST3400 TAWS. (A) Topographic mode of terrain indication. (B) Relative altitudes mode of terrain indication.

database of obstacles. In case of potential threat, TAWS provides sufficient warnings for pilots. In addition, a dangerous relief is indicated to the pilot to increase situational awareness. TAWS relief indication can be provided in two basic modes: topographic and relative altitudes. Both of these modes support the pilot with fast access to visual terrain data that clearly indicates an airplane's relation to the ground. In topographic mode, the terrain is displayed in green chart colors, except terrain above the current airplane altitude that is highlighted with red color. Relative altitude mode indicates terrain data in relative altitude to an airplane location. Relief progressively close to an airplane altitude is depicted as green, yellow, and red color table (Fig. 6).

International regulation of TAWS contains a detailed description of seven basic modes of operation:

Mode 1. Excessive rates of descent: At these modes, TAWS compares AGL from LRRA and excessive descending barometric altitude rate from air data system with predefined boundary curves (Fig. 7). In case of excessive descent rate, TAWS generates aural warning "Sink rate" or "Pull Up."

Mode 2. Excessive closure rate to the terrain: TAWS compares AGL rate from LRRA and terrain closure rate calculated by the change of altitude. In case of excessive close rate, TAWS generates "Terrain, Terrain" and "Pull Up" aural warning. Mode 2 is divided into two sub-modes, according to flight phase that is detected by flaps location: Mode 2A for en-route and approach and Mode 2B for landing. Each mode has a specific curve shape for warnings generation.

Mode 3. Negative climb rate or altitude loss after take-off: In this mode, TAWS alerts about altitude lost immediately after take-off. Alarming is grounded on comparison of AGL from LRRA and altitude loss. Value of altitude loss is calculated by integration of barometric altitude or corrected altitude from GNSS. If altitude loss is detected, caution alert "Don't sink" is generated.

Mode 4. Flight into the terrain when not in landing configuration: In this mode, TAWS compares AGL and airspeed with landing configuration of landing gear (sub-mode 4A) and flaps (sub-mode 4B). If AGL is less than 500 ft. (150 m) and landing gear is not in landing configuration, Mode 4A generates caution alert "Too low gear." If $AGL \leq 245$ ft. (75 m) and flaps are not in landing configuration, Mode 4B generates caution "Too low flaps." At the same configuration, but with high airspeed both sub-modes issue "Too low terrain" caution.

Mode 5. Excessive downward deviation from a glide path: This mode is active only in case of landing by ILS. TAWS analyses AGL and deviation below glideslope trajectory. In case of $AGL \leq 1000$ ft. (305 m) and deviation more than 1.5 dots, TAWS generates alert "Glideslope" in a soft manner, in case of $AGL \leq 300$ ft. and deviation more than 2 dots, it issues a hard alert.

Mode 6. Advisories and altitude callouts: During the landing phase or operation at low altitude, all pilots' attention is directed into instruments or setting of visual contact with runway and terrain around. Thus, voice callout of specific AGL altitude crossing improves vertical awareness of pilot, due to the terrain below of airplane. The most useful altitude callouts are 1000, 500, 300, 200, 100, 50, 40, 30, 20, and 10 ft. AGL. Some modifications of TAWS can include alarming of activation altitude of LRRA in 2500 ft. (760 m) in the form of "Radio altimeter" or "Twenty five hundred" voice callout. This message indicates that LRRA is active and AGL is available in the system. During the landing of the airplane, pilots need to exactly understand a moment of decision height crossing in the final approach procedure. The point of decision height is preselected by a pilot at relative height scale of the airplane (barometric or AGL) to runway altitude at which pilot has to make a decision about landing or fault landing and climbs in case of getting a second chance of approach. The fault of landing may be a result of pure visibility, bad weather conditions, windshear, excessive rate of descent, or other factors that cannot guaranty successful airplane landing. In Mode 6, TAWS generates voice alert "Decision height" or "Minimums," in case of crossing predefined decision height. Also, Mode 6 can include alarming about

Figure 7 TAWS modes. (A) Mode 1. Excessive rates of descent. (B) Mode 2. Excessive closure rate to the terrain. (C) Mode 3. Negative climb rate or altitude loss after take-off. (D) Mode 4. Flight into the terrain when not in landing configuration. (E) Mode 5. Excessive downward deviation from a glide path. (F) Mode 6. Excessive roll angle at low AGL altitude.

overbanking conditions, in case of significant airplane maneuvering with excessive roll angle at low AGL altitude, mostly below 150 ft. (45 m) with a roll angle more than ± 10 degree.

Mode 7. Windshear detection: Excessive windshear energy may cause a big threat to airplane operation at low altitude. Windshear is a sudden change of wind direction and velocity in different planes. The appearance of wind shear at low altitude degrades the performance of the airplane and may result in sudden altitude drop. Thus, an alarm indicating high magnitude of windshear is important for pilots during landing or for airplane operation at low altitude. Presence and magnitude of windshear can be detected by various algorithms that use different input data, such as wind, air, true, and vertical speeds; angle of attack; airplane acceleration components, and other on-board sensors data. Some sensors can use specific equipment to sense the speed of air particles ahead of the airplane. Mode 7 generates aural alert "Windshear, Windshear, Windshear," in case of windshear risk detection.

Regulative documents specify various curve shapes for different modes depending on TAWS type and implementation. Also, multiple TAWS aural alert can be prohibited in general settings of TAWS in order to follow airline best practice.

FLTA algorithm of TAWS uses airplane location and speed vector to extrapolate trajectory. The extrapolated trajectory is checked with terrain and obstacle models for a potential collision. Basically, the extrapolated airplane path is based on airplane location (latitude and longitude), heading angle, and ground speed. Altitude extrapolation is grounded on current airplane altitude from GNSS and vertical speed. Caution alert "Caution, Terrain" is generated in case of conflict detection between extrapolated airplane trajectory and terrain/obstacle elevation in 20 s ahead of the airplane. If the pilot does not take appropriate action, a warning alert "Terrain, Terrain. Pull up" will be issued in 10 s ahead of the conflict.

The premature descent alert (PDA) function of TAWS compares current airplane location with a predefined three-dimensional approach trajectory in order to detect an excessive airplane deviation with further generation of aural caution "Too Low Terrain."

Regulative documents specify two basic classes of TAWS:

- Class A TAWS must provide an indication of terrain on a display system and supports Modes 1–6.
- Class B TAWS does not require data display but must support modes 1, 3, and 6 only.

Classes A and B provide FLTA and PDA functions.

Nowadays TAWS is present in the equipment list of many airplanes, but the most important role of terrain collision awareness is in helicopter implementation. Helicopter missions are mostly connected with operation at low altitude, take off, and landing from the unequipped area, hovering, operation within natural, or artificial elements (Anderson et al., 2011). For example, in most emergency operations provided by a helicopter, pilot must fly to a place where he has never been before and lands in a place that is

not intended for landing. In such kind of missions, lack of terrain data or artificial environment plays an important role in successfully mission completion.

Basically, collision avoidance on board of airplane is grounded on system assistance in a generation of a set of advisories for pilots, requiring tacking actions from pilots in order to avoid mid-air collision or conflict with the terrain. Therefore, the human factor still plays an important role in the safety of aviation.

Biographies

Ivan Ostroumov has been a faculty of Air Navigation Systems Department of the National Aviation University of Ukraine since September 2007. He obtained his PhD degree of Engineering in Navigation and Traffic Control in 2009 from National Aviation University of Ukraine. Since then, he has been a research scientist and associated professor for National Aviation University. Since 2016, he has also served as navigation instructor at “Aviation Company Ukrainian Helicopters”. In 2017/2018, he was a Fulbright scholar in the school of Aeronautics and Astronautics at Purdue University, United States. He has also participated in several international projects, including Supporting SESAR on GNSS Vulnerability Assessment by performing Space Weather Analysis (Navigation department, EUROCONTROL, Brussel), and E-learning course development (Institute of Air Navigation Services, EUROCONTROL, Luxembourg). His research theme is advanced methods for Alternative Positioning, Navigation, and Timing. Current research projects include Methods and Algorithms of positioning by multiple navigational aids, Availability and Accuracy estimation of navigation.

Nataliia Kuzmenko is a senior researcher of the National Aviation University of Ukraine. She obtained her PhD degree of Engineering in Navigation and Traffic Control in 2017 from the National Aviation University of Ukraine. Nataliia is a certified aviation security instructor by ICAO (ASTP/Basic, ASTP/Instructors). She has had a traineeship in Tool Development for support to CAA/NSA at Regulatory Division within the Directorate Single Sky (Eurocontrol, Brussels). Current research projects include aviation safety, collision detection, and avoidance, artificial intelligence, Remotely Piloted Aerial Systems, video stream object detection and recognition, kernel density estimation, and neural networks.

A Need for Collision Avoidance Systems

According to the United States National Highway Traffic Safety Administration, 37,133 people died in 2017 in the United States alone due to automobile accidents (US Department of Transportation, 2018a). Worldwide estimates exceed 1.35 million fatalities each year and, based on projections by the World Health Organization, road accidents will become the fifth major cause of death by 2030 if the current trend continues. These figures stress the importance of developing and enforcing active measures to minimize car crashes. Automation and, specifically, the use of collision avoidance (World Health Organization, 2018) and warning systems (CAWSs) can help prevent road accidents. Recent studies have shown that over 90% of all vehicle crash fatalities are at least partly attributed to human-related factors, such as alcohol drinking, distraction, fatigue, and speeding (US Department of Transportation, 2018a). CAWSs can lift some of the responsibility (if not all) from the human driver and improve road safety by taking control of the automobile's actions when a collision is about to happen. Even non-autonomous measures such as pre-collision warnings, in which the driver is alerted about an impending crash event with no other action, have shown to significantly decrease the incidence and severity of accidents.

Brief History of Collision Avoidance and Warning Systems

CAWSs can be classified according to their level of autonomy. Non-autonomous systems, also known as collision warning systems (CWSs), are those that do not take control of the vehicle's driving functions but rather just alert the driver about potential collision threats via audio, visual, or haptic cues. Some CWSs can even suggest corrective measures to mitigate or avoid a crash. The first reported passenger automobile designed with a smart CWS was the Cadillac Cyclone XP-74, developed in 1959 by General Motors and seen in Fig. 1. The vehicle was equipped with two radar-based sensors near the headlights that would alert the driver of the proximity of frontal obstacles. The Cadillac Cyclone never saw mass-production and the concept of providing cars with such safety features had to wait until the early 1990s with the introduction of *Distance Warning* by Mitsubishi Debonair in Japan. This luxury car utilized a lidar to warn drivers about close-distance vehicles ahead. Other luxury cars, primarily in Japan and Europe, developed

Figure 2 Schematic representation of an ACC system.

similar safety features in the late 1990s and early 2000s. Nowadays, most modern vehicles provide customers with collision warning systems based on one or multiple proximity sensors such as cameras, lasers, and radars.

Autonomous and semi-autonomous on-board CAWSs are those that can either assist or take command of the automobile's braking or steering functions without human intervention. Herein, these systems will be simply referred to as collision avoidance systems (CASs) to distinguish them from CWSs. Up to the 1980s, most of the research on automobile safety focused on passive measures to protect the driver and passengers in the case of a crash such as crumple zones, seat belts, and airbags (Akamatsu et al., 2013). Studies at the time consistently showed a decrease in collision-related fatalities but an increase in road accidents. Recognizing that human factors were the leading cause of road related accidents, private and state initiatives in Europe (particularly, the Programme for European Traffic of Highest Efficiency and Unprecedented Safety, PROMETEUS), the United States, and Japan, stimulated the development of automation in transportation systems. The introduction of CASs to the market for civilian use started with the development of the adaptive cruise control (ACC) system in the late 1990s (Vahidi and Eskandarian, 2003). As illustrated in Fig. 2, ACC systems can detect the relative distance and velocity of vehicles ahead and self-regulate the distance between a vehicle and the vehicle in front. Early ACC models required the driver to set the car into ACC mode and, therefore, the functionality was not always in place during the duration of the drive. The first mass-produced automobile for sale to constantly use active forward collision avoidance was the Volvo XC60 in 2008. Volvo XC60 utilized a CAS named *City Safety* that monitored the distance of vehicles and pedestrian ahead and could automatically stop the vehicle and avoid hard collisions when traveling under 30 km/h. Nowadays, a wide variety of vehicles do not only provide forward CASs but can also assist the vehicle when in risk of rear and lateral collisions. Moreover, several companies are currently developing and testing vehicles capable of driving safely from start to end with minimal human supervision.

It should be noted that mobile robotics research paved the way for the development of CAWSs. Several universities, scientific institutes, and research governmental agencies, such as NASA, developed and tested collision avoidance algorithms and obstacle detection methods for unmanned vehicles, primarily, in the 1970s and 1980s (Rodríguez-Seda et al., 2014). However, the implementation of these methods in the automobile industry had to wait for the robotics technologies to mature. In contrast to early studies with unmanned vehicles, automobiles need to operate in highly uncertain and dynamic environments that require a higher level of precision, robustness, and safety not viable at the time.

Overview and Strategies of CASs

Operation of CASs depends on the vehicle's level of automation (according to SAE established levels) and capabilities (US Department of Transportation, 2018a). Most CASs utilize one or multiple proximity and localization sensors such as global

positioning systems (GPSs), lidars, short and long-range radars, and cameras. They monitor traffic as well the presence of nearby vehicles, pedestrians, animals, and objects and send their information to decision making units distributed around the car. The on-board decision making units, also known as electronic control units (ECUs), process the information from multiple sensors to make predictions about potential collisions and to suggest corrective actions. In lower automation level vehicles, the CAS may start by alerting the driver. If the driver does not respond, the system may take an autonomous action such as braking or steering. In more high-level cars, such as SAE Level 3, the decision to regulate the car and avert a collision can be made without human intervention.

The methods and policies employed by the CAS may be classified as cooperative or non-cooperative. A cooperative strategy is one in which all nearby vehicles and obstacles abide to the same set of safety rules and share the common goal of avoiding a crash. The rules may include a particular protocol to deal with intersections (which vehicle can continue and which vehicle needs to stop), merging or changing lanes, and reducing the velocity or accelerating the vehicle while platooning, among many others. Due to the diversity of automobile brands and models on today's roads and the need for high level of coordination among vehicles, practically all of today's collision safety systems assume a non-cooperative strategy.

Similarly, autonomous collision avoidance strategies can be classified as planned or reactive. A planned strategy is one in which the desired avoidance trajectory of the vehicle is computed in advance. It requires prior knowledge of the road and some level of coordination among vehicles and other obstacles in order to guarantee the safest course of action. Reactive strategies, on the other hand, update the vehicle's actions on-line, based on current information about the vehicle's environment. Reactive measures are in general more robust and reliable but, due to the lack of planning, their reaction to a collision threat may be unexpected or abrupt. Today's autonomous systems are typically a combination of both strategies.

Example of Current Technologies

The following technologies are examples of current CAWSs widely available in today's passenger cars. System names are based on the US department of transportation's definitions ([US Department of Transportation, 2018b](#)) and can vary among automakers.

ACC

An ACC system is one that regulates the velocity of the car to a desired constant speed but that can also adjust the velocity based on the distance of vehicles ahead. By using proximity sensors, it aims to keep a safe distance between the vehicles and avoid forward collisions ([Fig. 2](#)).

Forward Collision Warning (FWD), Automatic Emergency Braking (AEB), and Pedestrian AEB

A FCW system is one that monitors the speed of the vehicle, the speed of any vehicle or large obstacle ahead, and the distance between both using proximity sensors. Based on the distance and speeds of both cars, the system warns the driver about a potential collision, typically by the use of visual and audio cues. If the driver does not respond and the vehicle is equipped with an AEB system, the car may automatically stop or reduce the velocity. Pedestrian AEB systems work in similar fashion by constantly looking for the presence of people crossing in front of the vehicle. It then warns the driver or automatically applies the brake, depending on the scenario, in order to avoid an accident.

Rear Cross Traffic Alert (RCTA)

RCTA systems monitor the presence of upcoming traffic and, sometimes pedestrian and cyclist, from the side as the vehicle reverses. It warns the driver about a potential collision.

Blind Spot Detection (BSD)

By using radars or side-view cameras, BSD systems aim to detect and alert the driver about the presence of vehicles in the driver's blind spots. If the driver tries to make a turn toward one of these blind spots, the system may send a stronger alert or even impede the turn. This concept is illustrated in [Fig. 3](#).

Lane Departure Warning (LDW) and Lane Keeping (LK)

LDW systems typically track the lane markings on the road using a camera and send an audio, visual, or haptic alert to the driver if the vehicle starts drifting out of its lane. A vehicle equipped with a LK system utilizes the LDW alert to prevent the vehicle from drifting away either by steering or accelerating the wheels. Both systems aim to avoid accidents with vehicles in other lanes as well as rollovers when leaving the road.

Figure 3 Blind spot detection system.

Rear Cameras and Parking Assist

Rear-view or backup cameras are typically employed in parking maneuvers and provide visual feedback to the driver when the car is in reverse mode. They also provide both visual and audio cues that alert the driver of the proximity with obstacles including people and pets.

Sensors and State-Awareness Technologies

For a CAWS to make a prediction or decision, it needs to know the state of the car (velocity and position) and detect the presence of other vehicles and obstacles. To this end, it requires the use of on-board sensors, monitoring devices, or communication systems that can provide feedback to the driver or the car. The following is a list of common sensing and communication technologies in the automobile industry.

Radars, Lidars, and Sonars

Radars, lidars, and sonars are among the most common sensors used in CAWSs (Mukhtar et al., 2015). They are examples of active sensors that emit energy in order to compute distance. Radar, which is also known as *Radio Detection and Ranging*, emits electromagnetic waves. When the electromagnetic wave encounters an object it bounces back to the sensor. The time it takes the signal to travel back and forth and the Doppler shift experienced by the signal are then used to compute the relative distance and velocity of the other object. Similar to radars, a lidar or *Light Detection and Ranging*, emits pulses in various directions. When the pulses reach an object, they bounce back to the sensor. Differences in return times and wavelengths can be then used to estimate distances as well as 2D and even 3D representations of objects. Finally, active sonar, also known as *Sound Navigation Ranging*, creates sound waves. When the waves hit an object and bounce back to the sensor, their traveling time is used to estimate the object's relative distance.

Radars and lidars, along with cameras, are the most popular sensors for collision avoidance systems and when combined with multiple units or with actuators, they can provide a 360° degree view of the surrounding environment. In general, radars are typically better for longer distances and under low visibility conditions, whereas lidars are better in detecting smaller obstacles and in providing an accurate representation of the surrounding objects. Sonars tend to have longer delays and to be more sensitive to noise. Therefore, they are mostly used for parking assist systems and slow velocities maneuvers.

Cameras

Cameras are passive optical sensors mostly used to track and identify objects surrounding the vehicle. One or multiple cameras, more commonly of stereotype, take constant images of the environment. The images are then processed by computer vision algorithms that can not only estimate the distance but also can identify and classify the objects (e.g., pedestrians, vehicles, and trees). Current research trends in machine learning and computing are helping cameras to identify and classify objects with human-like abilities. To operate at night, infrared cameras are sometimes used.

GPS

Many of today's automobiles are equipped with GPS units. GPS units require at least three radio signals coming from three different GPS satellites. These signals carry the time and position information of the satellites, which then the GPS unit uses to estimate the location of the vehicle using triangulation. Today's systems require at least four satellite signals to provide accurate position information, which have error ranges in the few meters depending on the unit, number of satellite signals, location, and noise interference.

GPSs can only provide localization for the own vehicle. Therefore, it is mostly used for navigation systems and can only provide collision information in well-known environments as well as velocity estimation. They also require a fairly open sky, which limits their usability to low rise building areas and open roads (no tunnels). However, with the development of vehicle-to-vehicle (V2V) communication and vehicle-to-environment (V2X) communication, GPSs can assist CAWSs by sharing position information among vehicles.

V2V and V2X Communication

V2V communication refers to the wireless exchange of information, such as position, trajectory, and velocity, among vehicles. V2X, also known as vehicle-to-infrastructure (V2I), refers to the communication between vehicle and surrounding infrastructure. Common wireless communication networks include radio, internet, and cellular networks.

V2V and V2X applications can increase cooperation among vehicles and can inform the driver or the CAWS about road, traffic, and weather conditions. Intelligent highways and stationary smart sensors on the roadside can help coordinate vehicular flow such as in platooning and lane merging and increase traffic capacity and efficiency. The US department of transportation estimates the use of thousands of infrastructure V2X devices already installed in the US roads and a recent study from March 2019 projects nearly six million V2X-equipped vehicles worldwide by 2022 ([US Department of Transportation, 2018a](#)). Similarly, the European Union plans to require speed-limiting technology in all new car models starting in 2022. The cars will use GPS signals and V2X communication to identify speed limits and automatically regulate the vehicles' velocity.

Challenges

Despite the current capabilities and achievements in crash prevention, CAWSs face some unique challenges ranging from technological obstacles to societal concerns. Some of these challenges are currently evolving at the same pace as smart vehicles are hitting the road.

Sensor Faults and Errors

CAWSs need to be reliable under diverse operating conditions. They need to safely operate during daylight as well as dark, under fog and low visibility, snow, and rain. Typically, such issues are addressed by redundancy (i.e., the use of multiple sensors of different modalities) and by estimation of algorithms that can provide state awareness despite noisy or limited information. These measures and advances, however, can increase the cost of the vehicle, which can only be justified and financially sustained by appropriate market demand and by large public and private investment. In addition, even state-of-the-art sensor technologies can occasionally fail and health monitoring, security, and emergency systems must be in place to recognize and recover from such state. CASs need to take into consideration the effects of sensing errors and faults without being too conservative in order to preserve efficiency ([Rodríguez-Seda et al., 2016](#)).

Human Drivers Versus Machines

Computers and automated systems present several advantages over human drivers. First, automated systems can identify and respond to unexpected threats quicker than what a human driver would. Second, CAWSs can remain in alert mode during the entire duration of the trip without being subject to fatigue or distraction. On the other hand, human drivers are typically better in making decisions under unexpected and unplanned events and may be able to classify objects better than what a computer vision or lidar system can. However, the later advantages from the human driver are only a matter of time as current advances in computer vision and computing, specifically machine learning, have preliminary shown unprecedented performance that can challenge and overpass human capabilities.

Human Drivers and the Effect of Automation

Deployment of autonomous cars requires public acceptance and trust. When it comes to transportation systems, this typically involves keeping a human driver in the loop, which can supervise and override computer commands. Moreover, human drivers may still be required as a safety measure in case of system failures. Unfortunately, the reliance on automation may conversely yield human drivers less adept to safely respond to rare events. Take, for example, the aviation industry, which has pioneered the way for self-driving transportation systems. Accidents like the Air France Flight 447 in 2009, where pilots were unable to recognize and correct a dangerous state after the plane's autopilot disengaged, have shown how automation can limit the ability of pilots to respond to unexpected and rare events. Similarly, more recent events such as the Lion Air Flight 610 in 2018 and the Ethiopian Airlines Flight 302 in 2019 highlighted the need for pilots to better understand the operation of autonomous mechanisms as well as the transition between autonomous and non-autonomous behavior. Other examples of over reliance on automation more specific to the automobile industry include the Tesla Model S fatal crash in Williston, Florida in 2016, where the autopilot system failed to recognize a tractor-trailer and drove the car into it without braking at all, and the Uber self-driving Volvo CX90, which killed a

bicyclist in Tempe, Arizona in 2018. In both cases, the drivers were determined to be distracted and were not taking proper responsibility in controlling the car. Overall, if human drivers are expected to supervise or complement autonomous mechanisms, then standards for the training and regular assessment of human driver abilities must be developed and enforced.

System Integration

In addition to a potential loss of cognitive abilities due to over reliance on automation, studies have shown that human drivers may become immune or ignore some of the warning signs of CAWSs (Akamatsu et al., 2013). Specifically, there must be different alerts according to the severity of the threat, a reduction on the false alarm rate, and coordination among other types of warning signs. Specifically, CAWSs are just one part of a larger concept known as driver assistance systems (DASs). DASs integrate a wide range of automated or smart functions that aim to ease the driver workload and improve efficiency by increasing state-awareness or taking control of some driving functions. The latter means that CAWSs will be integrated with other smart functions, which may generate their own alerts. Coordination among multiple subsystems must be in place to avoid driver's confusion and reduce mental workload.

In addition, the driver must comprehend how the vehicle's safety systems work and, when operating in an autonomous mode, the vehicle must react in a way that either emulates the driver's natural or reasonable behavior. That is, the driver may lose confidence in the CAWS if the vehicle is perceived as behaving irrationally or in unexpected ways.

Cybersecurity

The use of smart systems and wireless communication technologies can present automakers as well as the government with a new set of challenges. Researchers at different universities have shown how the increasing connectivity and integration of automobiles can make today's vehicle vulnerable to remote interference (Petit and Shladover, 2014). Intruders and criminals can easily get access to the vehicle's main controller-area-network (CAN) Bus via any of the dozens (and sometimes, hundreds) of on-board ECUs and disrupt the operation, override control commands, and disable safety systems. Even tampering with or denying the system with critical sensor data, such as speedometers, can have unsafe consequence. Automakers need to put in place measures to prevent, identify, and contain the effect of cyber attacks. Today's automobiles are examples of cyber-physical systems and require safety measures atypical of standard information technology systems. Vehicles need to be constantly monitored for cyber intrusions and control units and software need to be frequently updated to keep up with current standards. Passwords need to be customized and regularly updated for each vehicle and ECU. Vehicles need to be equipped with fault detection systems that can also identify the tampering of data and with safety systems protocols that can contain the effect of an attack.

Public Perception, Ethical Challenges, and Legal Responsibility

Successful integration of CAWSs and other autonomous features on cars will highly depend on how the public and the government embrace the use of autonomy. In contrast to the aviation industry and mass-transit systems where the driver (or the lack of a driver) is hidden from the passengers' view, the lack of human control is quite evident and present to the passenger inside the car. The environment is also different and not as predictable as for planes or trains: cars do not have dedicated lanes and have to share the roads with thousands of other vehicles and objects of different sizes and shapes, including motorcycles, animals, and trucks. Any accident involving automation tends to receive significant media attention, which in turn, can increase public concern and set back the implementation of CASs despite their safety record. Examples such as the Tesla crash in 2016 and the Uber incident in 2018 delayed the testing and release of self-driving functions for both companies.

Similarly, the use of CAWSs raises several ethical and legal questions that are yet to be addressed. Whose safety does the system should prioritize under a potential collision threat? There might be instances where the system may need to choose among the driver, other drivers, passengers, cyclists, and pedestrians. Then, there is the challenge of responsibility and liability. In the case of an accident, is the driver responsible? Or is the vehicle's manufacturer, the autopilot's software, or the company that designed the faulty sensors is the one responsible? What kind of consequences and penalties should a company or a driver receive and how insurance companies will assess responsibility? Current state and federal laws were enacted with a driver in mind and, therefore, need to be adapted to properly regulate the operation of autonomous and semi-autonomous cars. As of 2019, there are still no federal strict regulations and uniform safety tests in place for the development and operation of autonomous cars in the United States.

Future Developments and Considerations

There is a very little doubt about the positive impact that automation can have on transportation safety. As an example, one can take a look at how automation revolutionized the aviation industry by making air transportation safer (Boyd, 2017). As for the automobile industry, it has been shown in several studies that CAWSs can reduce road accidents or mitigate the severity of a crash. For instance, a recent study in 2017 demonstrated that FCW, AEB, and FWC with AEB systems can reduce rear-end striking crashes by 27%, 43%, and 50%, respectively (Cicchino, 2017). Yet, there is unarguably room for improvement. The final goal is to have fully autonomous vehicles capable of driving with better precision, safety, and efficiency than human drivers under all scenarios and circumstances. To

this end, several automakers and research institutes are working toward more robust and reliable systems, which includes newer, better, and cheaper sensing technologies as well as more precise estimation and detection algorithms. Another research trust toward safer vehicle transportation is the integration of V2V and V2X communications and the development of intelligent highways that can better support autonomous systems and enable cooperation among vehicles. Cooperation among vehicles and the infrastructure enables not only efficiency but can also increase safety by coordinating routes and informing vehicles about hazard conditions on the road. Finally, research into evasive collision avoidance must continue. Current systems command the car to stop or reduce the velocity under a crash threat. Under some circumstance, a CAS should be able to safely steer away a car and avoid a collision without the need to stop.

In the meantime, while autonomous systems share control command with a human driver (even as a supervisory role), the public needs to be better informed about the operation and shortcomings of CAWSs. Current CAWSs are not made to fully substitute the driver and the driver's attention, although reduced, cannot be neglected. Similarly, in order to continue the path toward a vision of zero-collisions, automakers and governmental entities need to invest and incentivize autonomous technologies. Specifically, the government must seek to enforce some basic, uniform autonomous measures of collision avoidance in all new cars. See also, Automobile Accidents and Passive Prevention Systems.

Introduction

The demand for transport in society is governed by several factors, including population size, demographics, urbanization, and economic development. In recent years, we have seen an increase in transport needs around the world. In connection with this, increasing demands are placed on sustainable transports, increased accessibility and gender equality in the transport system.

To meet these demands, both passenger and freight transport are expected to shift toward electrification, automation, connectivity, and shared services in the coming decades, with the ultimate goal of increasing the transport efficiency, availability, and safety. The recent decades have thus witnessed a rapid evolution of both automated vehicles (AV) and connected vehicles (CV), and a gradual merge of these two paths into connected automated vehicles (CAVs).

This chapter reports first a brief introduction of AVs and CVs, their current development and main enabling technologies, followed by their integration into CAVs. While we acknowledge importance of all levels of automation, this chapter has an emphasis on the higher levels of automation.

Automated Vehicles

An automated vehicle (AV) is a vehicle in which an automated driving system (ADS) performs parts or entire dynamic driving task. Here, a dynamic driving task includes all real-time operational and tactical functions required to drive a vehicle in road traffic,

Figure 1 Major milestones in the development of automated driving.

excluding strategic functions, such as route planning. Today, various nomenclature is used for AVs, where a few of the most common ones are “autonomous,” “self-driving,” “robotic,” and “driverless” vehicles.

A Brief History of Automated Driving

Development of AVs dates back to around 1478 when Leonardo da Vinci designed a cart that could move without being pushed or pulled (Fig. 1). Centuries later, in 1939, General Motors displayed a vision of the future that included an automated highway system. In 1958, the company turned its vision into a prototype. However, it took several decades until AVs become a serious option for transportation. Automated vehicles developed within the project PROMETHEUS (1987–95) and DARPA Challenge (2004, 2007) are seen as key precursors of the AVs that we have under development today.
